## 1 Preface

2 This document describes the information requirements under the REACH Regulation with  
3 regard to substance properties, exposure, uses and risk management measures, and the  
4 chemical safety assessment. It is part of a series of guidance documents that are aimed  
5 to help all stakeholders with their preparation for fulfilling their obligations under the  
6 REACH Regulation. These documents cover detailed guidance for a range of essential  
7 REACH processes as well as for some specific scientific and/or technical methods that  
8 industry or authorities need to make use of under the REACH Regulation.

9

10 The original versions of the guidance documents were drafted and discussed within the  
11 REACH Implementation Projects (RIPs) led by the European Commission services,  
12 involving stakeholders from Member States, industry and non-governmental  
13 organisations. After acceptance by the Member States competent authorities the  
14 guidance documents had been handed over to ECHA for publication and further  
15 maintenance. Any updates of the guidance are drafted by ECHA and are then subject to  
16 a consultation procedure, involving stakeholders from Member States, industry and non-  
17 governmental organisations. For details of the consultation procedure, please see:

18 [http://echa.europa.eu/documents/10162/13608/mb\\_63\\_2013\\_revision\\_consultation\\_pr  
19 ocedure\\_guidance\\_en.pdf](http://echa.europa.eu/documents/10162/13608/mb_63_2013_revision_consultation_procedure_guidance_en.pdf)

20

21 The guidance documents can be obtained via the website of the European Chemicals  
22 Agency at:

23 <http://echa.europa.eu/web/guest/guidance-documents/guidance-on-reach>

24 Further guidance documents will be published on this website when they are finalised or  
25 updated.

26

27 This document relates to the REACH Regulation (EC) No 1907/2006 of the European  
28 Parliament and of the Council of 18 December 2006<sup>1</sup>.

29

---

<sup>1</sup> Regulation (EC) No 1907/2006 of the European Parliament and of the Council of 18 December 2006 concerning the Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH), establishing a European Chemicals Agency, amending Directive 1999/45/EC and repealing Council Regulation (EEC) No 793/93 and Commission Regulation (EC) No 1488/94 as well as Council Directive 76/769/EEC and Commission Directives 91/155/EEC, 93/67/EEC, 93/105/EC and 2000/21/EC (OJ L 396, 30.12.2006, p.1; corrected by OJ L 136, 29.5.2007, p.3).

1 Document history

| Version     | Changes  | Date          |
|-------------|--|---------------|
| Version 1   | First edition  | July 2008     |
| Version 1.1 | Corrigendum:<br><br>(i) replacing references to DSD/DPD by references to CLP<br><br>(ii) further minor editorial changes/corrections   | November 2012 |
| Version 2.0 | Second edition. Partial revision of this document was necessary to take into account the revised version (2.0) of Chapter R.11 of the Guidance on IR&CSA following amendment of Annex XIII to REACH (according to Commission Regulation (EU) No 253/2011 of 15 March 2011, OJ L 69 7 16.3.2011). Main changes in the guidance document include the following: <ul style="list-style-type: none"> <li>• References to the updated Chapter R.11 have been added and the corresponding text updated;</li> <li>• The document has been re-formatted to ECHA new corporate identity.</li> </ul> | November 2014 |
| Version 3.0 | Partial revision of the document with respect to PBT/vPvB aspects to take into account the updated version of Chapter R.11 (v 3.0). Main changes in the guidance document include the following: <ul style="list-style-type: none"> <li>• Update to Section R.7.10.1: XX</li> <li>• Update to Section R.7.10.3.1: <i>in vitro</i> bioaccumulation assessment XXX</li> <li>• Update to Section R.7.10.8 to R.7.10.13: XXX</li> <li>•</li> </ul>   | XXX 201X      |

## Table of Contents

|    |   |           |
|----|---|-----------|
| 1  | <b>Table of Contents</b>  |           |
| 2  | <b>R.7.10 Bioconcentration and bioaccumulation; long-term toxicity to</b>                 |           |
| 3  | <b>birds</b> .....  | <b>10</b> |
| 4  | <b>R.7.10.1 Aquatic bioaccumulation</b> .....   | <b>10</b> |
| 5  | R.7.10.1.1 Definitions of aquatic bioaccumulation.....                                    | 10        |
| 6  | R.7.10.1.2 Objective of the guidance on aquatic bioaccumulation .....                     | 12        |
| 7  | <b>R.7.10.2 Information requirements for aquatic bioaccumulation</b> .....                | <b>12</b> |
| 8  | <b>R.7.10.3 Available information on aquatic bioaccumulation</b> .....                    | <b>12</b> |
| 9  | R.7.10.3.1 Laboratory data on aquatic bioaccumulation.....                                | 13        |
| 10 | R.7.10.3.2 Non-testing data aquatic bioaccumulation.....                                  | 21        |
| 11 | R.7.10.3.3 Field data on aquatic bioaccumulation .....                                    | 26        |
| 12 | R.7.10.3.4 Other indications of bioaccumulation potential.....                            | 28        |
| 13 | <b>R.7.10.4 Evaluation of available information on aquatic bioaccumulation</b> .....      | <b>31</b> |
| 14 | R.7.10.4.1 Laboratory data on aquatic bioaccumulation.....                                | 31        |
| 15 | R.7.10.4.2 Non-testing data on aquatic bioaccumulation .....                              | 40        |
| 16 | R.7.10.4.3 Field data on aquatic bioaccumulation .....                                    | 43        |
| 17 | R.7.10.4.4 Other indications of bioaccumulation potential.....                            | 45        |
| 18 | R.7.10.4.5 Exposure considerations for aquatic bioaccumulation .....                      | 46        |
| 19 | R.7.10.4.6 Remaining uncertainty for aquatic bioaccumulation.....                         | 46        |
| 20 | <b>R.7.10.5 Conclusions for aquatic bioaccumulation</b> .....                             | <b>48</b> |
| 21 | R.7.10.5.1 Concluding on suitability for Classification and Labelling .....               | 53        |
| 22 | R.7.10.5.2 Concluding on suitability for PBT/vPvB assessment .....                        | 53        |
| 23 | R.7.10.5.3 Concluding on suitability for use in Chemical Safety Assessment ....           | 53        |
| 24 | <b>R.7.10.6 Integrated Testing Strategy (ITS) for aquatic bioaccumulation</b> .....       | <b>54</b> |
| 25 | R.7.10.6.1 Objective / General principles.....  | 54        |
| 26 | R.7.10.6.2 Preliminary considerations .....   | 55        |
| 27 | R.7.10.6.3 Testing strategy for aquatic bioaccumulation.....                              | 55        |
| 28 | <b>R.7.10.7 References for aquatic bioaccumulation</b> .....                              | <b>57</b> |
| 29 | <b>R.7.10.8 Terrestrial Bioaccumulation</b> .....   | <b>72</b> |
| 30 | R.7.10.8.1 Definitions and metrics used in terrestrial bioaccumulation .....              | 72        |
| 31 | R.7.10.8.2 Objective of the guidance on terrestrial bioaccumulation .....                 | 74        |
| 32 | <b>R.7.10.9 Information requirements for terrestrial bioaccumulation</b> .....            | <b>74</b> |
| 33 | <b>R.7.10.10 Available information on terrestrial bioaccumulation</b> .....               | <b>74</b> |
| 34 | <b>R.7.10.11 Evaluation of available information on terrestrial bioaccumulation</b> ..... | <b>78</b> |
| 35 | R.7.10.11.1 Field data .....  | 80        |
| 36 | R.7.10.11.2 Exposure considerations for terrestrial bioaccumulation.....                  | 80        |
| 37 | <b>R.7.10.12 Conclusions for terrestrial bioaccumulation</b> .....                        | <b>80</b> |
| 38 | R.7.10.12.1 Concluding on suitability for Classification and Labelling .....              | 82        |
| 39 | R.7.10.12.2 Concluding on suitability for PBT/vPvB assessment .....                       | 82        |
| 40 | R.7.10.12.3 Concluding on suitability for use in Chemical Safety Assessment ....          | 82        |
| 41 | <b>R.7.10.13 Integrated testing strategy (ITS) for terrestrial bioaccumulation</b> ...    | <b>82</b> |
| 42 | R.7.10.13.1 Objective / General principles.....   | 82        |
| 43 | R.7.10.13.2 Preliminary considerations .....  | 83        |
| 44 | R.7.10.13.3 Testing strategy for terrestrial bioaccumulation .....                        | 83        |
| 45 | <b>R.7.10.14 References for terrestrial bioaccumulation</b> .....                         | <b>83</b> |
| 46 | <b>R.7.10.15 Mammalian toxicokinetic data in bioaccumulation assessment</b> .....         | <b>86</b> |

## R.7.10 Bioconcentration and bioaccumulation; long-term toxicity to birds

### R.7.10.1 Aquatic bioaccumulation

Information on accumulation in aquatic organisms is vital for understanding the environmental behaviour of a substance, and is a relevant consideration at all supply levels, even when it is not a specified requirement. The information is used for hazard classification and PBT assessment as well as wildlife and human food chain exposure modelling for the chemical safety assessment. It is also a factor in deciding whether long-term ecotoxicity testing might be necessary. This is because chemical accumulation may result in internal concentrations of a substance in an organism that cause toxic effects over long-term exposures even when external concentrations are very small. Highly bioaccumulative chemicals may also transfer through the food web, which in some cases may lead to biomagnification.

#### R.7.10.1.1 Definitions of aquatic bioaccumulation

Several terms have been used to describe chemical accumulation in biota, and slightly different definitions of these (all of equal validity) may be found in the literature. For the purposes of this document the following definitions have been used:

*Accumulation* is a general term for the net result of absorption (uptake), distribution, metabolism and excretion (ADME) of a substance in an organism. These processes are discussed in detail in the mammalian toxicokinetics guidance document. In aquatic organisms, the main removal processes – referred to as elimination or depuration – is diffusive transfer across gill surfaces and intestinal walls, and biotransformation to metabolites that are more easily excreted than the parent compound. Further discussion of aquatic bioaccumulation processes may be found in other reference sources such as ECETOC (1996) and Boethling and Mackay (2000). Maternal transfer to eggs may add to depuration and can sometimes be significant, while growth may affect the concentration in an organism in the case when the rate of other excretion processes is in the same order of magnitude as the growth (dilution) rate.

*Bioconcentration* refers to the accumulation of a substance dissolved in water by an aquatic organism. Annex 1 of OECD test guideline (TG) 305 contains definitions for BCF. The steady-state *bioconcentration factor* ( $BCF_{SS}$ ) is the ratio of the concentration of a substance in an organism to the concentration in water once a steady state has been achieved:

$$BCF_{SS} = C_o/C_w$$

where BCF is the bioconcentration factor (L/kg)

$C_o$  is the chemical concentration in the whole organism (mg/kg, wet weight)

$C_w$  is the chemical concentration in water (mg/L)

Please note that corrections for growth and/or a standard lipid content are not accounted for in this definition of the BCF.

1 The steady-state bioconcentration factor ( $BCF_{SS}$ ) does not change significantly over a  
2 prolonged period of time, the concentration of the test substance in the surrounding  
3 medium being constant during this period.

4 Assuming that the organism can be mathematically represented as a homogeneously  
5 mixed single compartment (Sijm, 1991), and that first order kinetics applies, a BCF can  
6 also be expressed on a kinetic (i.e. non-equilibrium) basis as the quotient of the uptake  
7 and depuration rate constants:

$$8 \quad \text{(Kinetic) } BCF_K = k_1/k_2$$

9 where  $k_1$  is the uptake clearance [rate constant] from water (L/kg/day)

10  $k_2$  is the elimination rate constant ( $\text{day}^{-1}$ ).

11 In principle the value of the  $BCF_{SS}$  and the  $BCF_K$  for a particular substance should be  
12 comparable, but deviations may occur if steady-state was uncertain or if corrections for  
13 growth have been applied to the kinetic BCF.

14 *Bioaccumulation* refers to uptake from all environmental sources including water, food  
15 and sediment. The *bioaccumulation factor* (BAF) can be expressed for simplicity as the  
16 steady-state (equilibrium) ratio of the substance concentration in an organism to the  
17 concentration in the surrounding medium (e.g. water in natural ecosystems).

18 For sediment dwellers, the biota-sediment accumulation factor BSAF is the ratio of the  
19 concentrations in the organism and the sediment. This may be normalised by  
20 multiplication with the quotient of the fraction of organic carbon of the sediment and the  
21 fraction of lipid in the invertebrate ( $f_{oc}/f_{lip}$ ), in which case the term is referred to as the  
22 normalised biota-sediment accumulation factor (BSAF).

23 *Biomagnification* refers to accumulation via the food chain. It may be defined as an  
24 increase in the (fat-adjusted) internal concentration of a substance in organisms at  
25 succeeding trophic levels in a food chain. The biomagnification potential can be  
26 expressed as either:

27 a *trophic magnification factor* (TMF), which is the concentration increase in organisms  
28 with an increase of one trophic level (Fisk *et al.*, 2001); or

29 a *biomagnification factor* (BMF), which is the ratio of the concentration in the predator  
30 and the concentration in the prey:

$$31 \quad BMF = C_o/C_d$$

32 where BMF is the biomagnification factor (dimensionless)

33  $C_o$  is the steady-state chemical concentration in the organism (mg/kg)

34  $C_d$  is the steady-state chemical concentration in the diet (mg/kg).

35 Whereas BMFs describe the increase in concentrations from prey to predator, TMFs  
36 describe the average increase in concentration per trophic level.

37

1 *Trophic dilution* occurs when the concentration of a chemical in a predator is lower than  
2 that in its prey (due to greater metabolic capacity and increased compartmentalization of  
3 higher trophic level species, etc.).

4 *Secondary poisoning* refers to the toxic effects in the higher members of a food chain  
5 that result from ingestion of organisms from lower trophic levels that contain  
6 accumulated substances (and/or related metabolites).

7 In all of the above equations, the concentration in the organism should be expressed on  
8 a wet (rather than dry) weight basis. In addition, it is important to consider lipid  
9 normalisation and growth correction in some circumstances and these are considered  
10 further in Section [R.7.10.4](#) and [R.7.10.5](#).

### 11 **R.7.10.1.2 Objective of the guidance on aquatic bioaccumulation**

12 The aim of this document is to provide guidance to registrants on the assessment of all  
13 available data on a substance related to aquatic bioaccumulation, to allow a decision to  
14 be made on the need for further testing.

### 15 **R.7.10.2 Information requirements for aquatic bioaccumulation**

16 Annex IX to REACH indicates that information on bioaccumulation in aquatic – preferably  
17 fish – species is required for substances manufactured or imported in quantities of 100  
18 t/y or more. In general, this means the establishment of a fish bioconcentration factor,  
19 although a biomagnification factor may also be appropriate in some circumstances.

20 Reliable measured data are preferred if available (see Section [R.7.10.5](#)), but Annex XI to  
21 REACH also applies, encouraging the use of alternative information at all supply levels  
22 before a new vertebrate test is conducted. Prediction techniques are well developed for  
23 many classes of organic substance (see Section [R.7.10.3](#)), and surrogate information  
24 (e.g. the octanol-water partition coefficient or  $K_{ow}$ ) may sometimes suffice on its own or  
25 as part of a *Weight-of-Evidence* approach. A number of new methods are also being  
26 developed, which may provide important alternative data in the future. These are  
27 summarised in Section [R.7.10.3](#).

28 Although bioaccumulation is not a specified endpoint below 100 t/y, surrogate  
29 information may still be relevant (e.g. for hazard classification and PBT screening), and  
30 more detailed consideration might be appropriate in some circumstances (see Section  
31 [R.7.10.5](#)). Furthermore, if a registrant, while conducting a CSA, cannot derive a  
32 definitive conclusion (i) (“The substance does not fulfil the PBT and vPvB criteria”) or (ii)  
33 (“The substance fulfils the PBT or vPvB criteria”) in the PBT/vPvB assessment using the  
34 relevant available information, he must, based on section 2.1 of Annex XIII to REACH,  
35 generate the necessary information, regardless of his tonnage band (for further details,  
36 see Chapter R.11 of the *Guidance on IR&CSA*). In such a case, the only possibility to  
37 refrain from testing or generating other necessary information is to treat the substance  
38 “as if it is a PBT or vPvB” (see Chapter R.11 of the *Guidance on IR&CSA* for details).

### 39 **R.7.10.3 Available information on aquatic bioaccumulation**

40 The following sections summarise the types of relevant data that may be available from  
41 laboratory tests or other sources. It should be noted that most of the methods were  
42 developed for neutral (i.e. non-ionised) organic chemicals, and there may be problems

1 applying some of the concepts to other substances – further guidance is provided in  
2 Section [R.7.10.4](#).

3 Several databases exist that summarise such information on a large number of  
4 substances, and the more important ones are described in [Appendix R.7.10-1](#).

5

### 6 **R.7.10.3.1 Laboratory data on aquatic bioaccumulation**

#### 7 ***In vivo* tests for aquatic bioaccumulation**

##### 8 Fish bioconcentration test

9 Traditionally, bioconcentration potential has been assessed using laboratory experiments  
10 that expose fish to the substance dissolved in water. A number of standardised test  
11 guidelines are available. The current EU C.13 method is based on the OECD test  
12 guideline (TG) 305, 1996, which was updated in October 2012 and is briefly described  
13 below. The OECD TG 305 (OECD, 2012a) is the most widely used test guideline. Other  
14 guidelines such as ASTM E1022-94 (ASTM, 2003) and the public draft guideline OPPTS  
15 850.1730 (US EPA, 1996a) are very similar<sup>2</sup>.

16 The revised OECD TG 305 (OECD, 2012a) provides guidance for the following three tests  
17 with different exposure methods and sampling schemes:

- 18 • OECD TG 305-I: Aqueous Exposure Bioaccumulation Fish Test
- 19 • OECD TG 305-II: Minimised Aqueous Exposure Fish Test
- 20 • OECD TG 305-III: Dietary Exposure Bioaccumulation Fish Test

21 The main changes in the revised test guideline compared to the previous version of  
22 OECD TG 305 from 1996 are the following:

- 23 • The testing of only one test concentration can be considered sufficient, when it is  
24 likely that the bioconcentration factor (BCF) is independent of the test  
25 concentration.
- 26 • A minimised aqueous exposure test design in which a reduced number of sample  
27 points is possible, if specific criteria are met.
- 28 • Fish lipid content should be measured so that BCF can be expressed on a lipid-  
29 normalised basis, as well as normalised to a 5% lipid content to allow  
30 comparison with other studies.
- 31 • Greater emphasis on kinetic BCF estimation (when possible) next to estimating  
32 the BCF at steady state.

---

<sup>2</sup> The main differences concern the: (a) method of test water supply (static, semi-static or flow through); (b) requirement for carrying out a depuration study; (c) mathematical method for calculating BCF; (d) sampling frequency; (e) number of measurements in water and number of samples of fish; (f) requirement for measuring the lipid content of the fish; and (g) minimum duration of the uptake phase.

- 1 • For certain groups of substances, a dietary exposure test will be proposed, where  
2 this is considered more suitable than an aqueous exposure test.
- 3 • Fish weight should be measured at least at the start and end of the study so that  
4 BCF<sub>K</sub> can be corrected for growth dilution.

5 In principle, a sufficient number of fish are exposed to one or two sub-lethal  
6 concentrations of the test substance dissolved in water. Both fish and water are sampled  
7 at regular time-intervals and the concentration of test substance measured. Tests are  
8 generally conducted using a flow-through system, although a renewal system is allowed  
9 if the requirement of constant aqueous concentration is met (flow-through methods are  
10 preferred for hydrophobic substances (i.e.  $\log K_{ow} > 3$ )). After reaching an apparent  
11 steady-state concentration (or after 28 days, whichever is sooner), the remaining fish  
12 are transferred to clean water and the depuration is followed<sup>3</sup>. For substances following  
13 first order kinetics, a period of half the duration of the uptake phase is sufficient for an  
14 appropriate (e.g. 95%) reduction in the body burden of the substance to occur. If a  
15 steady-state is not achieved within 28 days, either the BCF is calculated using the kinetic  
16 approach or the uptake phase can be extended.

17 Paragraphs 49-51 of the OECD TG 305 explains the conditions under which use of a  
18 single exposure concentration is possible and further guidance is available in OECD,  
19 2016. The main benefit of the single concentration bioconcentration test is it uses fewer  
20 fish than the two concentration test. Therefore there are animal welfare benefits in  
21 performing the single concentration test.

22 The aim of the aqueous bioconcentration testing is to produce a reliable estimate of how  
23 much substance could concentrate from the aquatic compartment ( $C_w$ ) to fish ( $C_f$ ) so  
24 that a bioconcentration factor (BCF<sub>SS</sub>) can be calculated by using the ratio  $C_f/C_w$  at  
25 steady-state. However, a BCF<sub>K</sub> value is preferred, and it may also be calculated as the  
26 ratio of the uptake rate constant ( $k_1$ ) and the depuration rate constant ( $k_2$ ). The revised  
27 OECD TG 305 (OECD, 2012a) contains a procedure for growth correction. The guideline  
28 regarding aqueous exposure (i.e. OECD TG 305-I and 305-II) is most validly applied to  
29 substances with  $\log K_{ow}$  values between 1.5 and 6. Practical experience suggests that if  
30 the aqueous solubility of the substance is low (i.e. below ~0.01 to 0.1 mg/L), this test  
31 might not provide a reliable BCF because it is very difficult to maintain exposure  
32 concentrations (Verhaar *et al.*, 1999). Volatile and degradable substances are also  
33 difficult to test with this method for similar reasons. This is the reason for flow-through  
34 testing in these situations.

#### 35 Previous OECD TG 305 (OECD, 1996)

36 The 1996 OECD guideline consolidates five earlier guidelines (A-E) (OECD, 1981) into a  
37 single revised method. If data have been obtained with one of these earlier guidelines,  
38 the method should be compared to the consolidated version to determine if any

---

<sup>3</sup> The time needed for reaching steady-state conditions may be set on the basis of  $K_{ow} - k_2$  correlations (e.g.  $\log k_2 = 1.47 - 0.41 \log K_{ow}$  (Spacie & Hamelink, 1982) or  $\log k_2 = 1.69 - 0.53 \log K_{ow}$  (Gobas *et al.*, 1989)). The expected time (in days) needed to achieve 95% steady state may be calculated as  $-\ln(1-0.95)/k_2$ , provided that the bioconcentration follows first order kinetics.

1 significant differences exist (e.g. the current guideline no longer recommends the  
2 enhancement of solubility by using dispersants).

3 A related approach is the *Banerjee method* (Banerjee, 1984), which assumes that the  
4 decline in measured aqueous concentrations of a test substance in a static exposure test  
5 system is due to accumulation by fish (the estimated increase in fish tissue  
6 concentrations being calculated as a mass-balance). An adaptation called the *adjusted*  
7 *Banerjee method* includes monitoring of fish concentrations as well (de Maagd, 1996).

#### 8 Fish dietary bioaccumulation test

9 The ring testing for the fish dietary bioaccumulation test has been published (OECD,  
10 2012b). In fish dietary exposure tests, a sufficient number of fish are exposed usually to  
11 one sub-lethal concentration of the test substance spiked in fish food. Both fish and food  
12 are sampled at regular time intervals and the concentration of test substance measured.  
13 It is recommended to conduct the test using a flow-through system in order to limit  
14 potential exposure of the test substance via water as a result of any desorption from  
15 spiked food or faeces. However, semi-static conditions are also allowed. An uptake phase  
16 of 7-14 days is recommended but it can be extended if necessary. As fish may not reach  
17 steady-state during the uptake phase, the data treatment and results are usually based  
18 on a kinetic analysis of tissue residues. This lack of steady state may also apply to the  
19 BMF measured for any reference substances used in the test. The depuration phase  
20 begins when the fish are fed for the first time with unspiked food and usually lasts for up  
21 to 28 days or until the test substance can no longer be quantified in whole fish,  
22 whichever is sooner. It is important to remove any uneaten food and faeces shortly after  
23 feeding to avoid the test substance partitioning to the water and thus exposure via the  
24 water.

25 A dietary exposure test (OECD TG 305-III: Dietary Exposure Bioaccumulation Fish Test)  
26 should be considered for substances for which it is not possible to maintain and measure  
27 aqueous concentrations reliably and/or potential bioaccumulation may be predominantly  
28 expected from uptake via feed. As indicated in the OECD TG 305, for strongly  
29 hydrophobic substances ( $\log K_{ow} > 5$  and a water solubility below  $\sim 0.01$ - $0.1$  mg/L),  
30 testing via aqueous exposure may become increasingly difficult. However, an aqueous  
31 exposure test is preferred for substances that have a high  $\log K_{ow}$  but still appreciable  
32 water solubility with respect to the sensitivity of available analytical techniques, and for  
33 which the maintenance of the aqueous concentration as well as the analysis of these  
34 concentrations do not pose any constraints. Also, if the expected fish concentration  
35 (body burden) *via* water exposure within 60 days is expected to be below the detection  
36 limit, the dietary test may provide an option to achieve body burdens that exceed the  
37 detection limits for the substance. As such, the principle idea of the dietary test is to  
38 obtain a depuration rate constant for substances for which this is impossible via the  
39 aqueous exposure route. However, an improved analytical technique, e.g. solid phase  
40 microextraction (SPME) and the use of a radiolabelled substance could be considered  
41 first to improve the detection limit in the aqueous test. The endpoint for a dietary study  
42 is a dietary biomagnification factor (dietary BMF), which is the concentration of a  
43 substance in predator (i.e. fish) relative to the concentration in the prey (i.e. food) at  
44 steady state. The dietary test also provides valuable toxicokinetics data including the  
45 dietary chemical absorption efficiency and the whole body elimination rate constant ( $k_2$ )  
46 and half-life.

47 More information on the fish dietary bioaccumulation test and the use of the results from  
48 it in the PBT assessment can be found in the Chapter R.11 of the Guidance on IR&CSA.  
49 Further information about interpretation of these studies is available in Section  
50 [R.7.10.4.1](#) and in OECD (2016).

1

2 Invertebrate tests

3 Invertebrate accumulation studies generally involve sediment-dwelling species (such as  
4 annelids (oligochaetes) and insects), although molluscs may also be tested. Like the fish  
5 dietary test, spiking of sediment circumvents exposure problems for poorly soluble  
6 substances. Several standardised guidelines exist or are in development.

7 OECD TG 315 Bioaccumulation in Sediment-dwelling Benthic Oligochaetes is the  
8 preferred method for generating bioaccumulation information in invertebrates. The  
9 recommended oligochaeta species are *Tubifex tubifex* (Tubificidae) and *Lumbriculus*  
10 *variegatus* (Lumbriculidae). The species *Branchiura sowerbyi* (Tubificidae) is also  
11 indicated but it should be noted that it has not been validated in ring tests at the time of  
12 writing. The biota-sediment accumulation factor (expressed in kg wet (or dry)  
13 sediment·kg<sup>-1</sup> wet (or dry) worm) is the main relevant outcome and can be reported as a  
14 steady state bioaccumulation factor BAF<sub>SS</sub> or as the kinetic biota-sediment accumulation  
15 factor (BSAF<sub>K</sub>). In both cases the sediment uptake rate constant  $k_s$  (expressed in kg wet  
16 (or dry) sediment·kg<sup>-1</sup> of wet (or dry) worm d<sup>-1</sup>), and elimination rate constant  $k_e$   
17 (expressed in d<sup>-1</sup>) should be reported as well. The normalised biota-sediment  
18 accumulation factor (BSAF) is the lipid-normalised steady state factor determined by  
19 normalising the BSAF<sub>K</sub> and should be additionally reported for highly lipophilic  
20 substances.

21 OECD TG 315 recommends the use of artificial sediment. If natural sediments are used,  
22 the sediment characteristics should be specifically reported. For lipophilic substances,  
23 BSAFs often vary with the organic carbon (OC) content of the sediment. Typically a  
24 substance will have greater availability to the organism when the sediment OC content is  
25 low, compared to a higher OC content. It should be considered to test at least two  
26 natural sediments with different organic matter content, the characteristics of the  
27 organic matter, in particular the content of black carbon, should be reported. To ensure  
28 comparability of results between different sediments, a normalised BSAF is derived from  
29 a non-normalised BSAF by converting the results to a standard OC content of 2%. This  
30 value is chosen based on the standard artificial sediment used in OECD sediment toxicity  
31 tests. This allows tests on the same substance and tests on different substances to be  
32 comparable. The load rate should be as low as possible and well below the expected  
33 toxicity, however it should be sufficient to ensure that the concentrations in the sediment  
34 and in the organisms are above the detection limit throughout the test. The relevance of  
35 bioavailability of the substance for the test organism should also be considered. In  
36 (normal) cases, when accumulation from the porewater is expected to dominate,  
37 bioaccumulation could be expressed as a BCF between organism and dissolved pore  
38 water concentrations.

39 ASTM E1022-94 describes a method for measuring bioconcentration in saltwater bivalve  
40 molluscs using the flow-through technique (ASTM, 2003). It is similar to the OECD TG  
41 305, with modifications for molluscs (such as size, handling and feeding regime).  
42 Consequently it has similar applicability. Results should be reported in terms of total soft  
43 tissue as well as edible portion, especially if ingestion of the test material by humans is a  
44 major concern. For tests on organic and organometallic chemicals, the percent lipids of  
45 the tissue should be reported. Recommended species are Blue Mussel (*Mytilus edulis*),  
46 Scallop (*Pecten* spp.) and Oyster (*Crassostrea gigas* or *C. virginica*). A similar test is  
47 described in OPPTS 850.1710 (US-EPA, 1996b).

48 ASTM E1688-00a (ASTM, 2000) describes several bioaccumulation tests with spiked  
49 sediment using a variety of organisms (some of these are also covered by US-EPA

1 guidelines), including: freshwater amphipods (*Diporeia sp.*), midge larvae (*Chironomus*  
2 *tentans*) and mayflies (*Hexagenia sp.*). Many of these are based on techniques used in  
3 successful studies and expert opinion rather than a specific standard method. The small  
4 size of many of these organisms sometimes means that large numbers of individuals are  
5 required for chemical analyses. Further useful information on sediment testing can be  
6 found in US-EPA (2000a).

7 In addition, non-standard tests may be encountered in the scientific literature, involving  
8 many species. Some information on uptake may also be available from sediment  
9 organism toxicity tests if tissue analysis is performed. However, a test specifically  
10 designed to measure uptake is preferable.

11

### 12 ***In vitro* data on aquatic bioaccumulation**

13 Procedures used to estimate intrinsic hepatic clearance from *in vitro* assay data were  
14 originally developed by the pharmaceutical industry to support preclinical screening of  
15 drug candidates (Rodrigues, 1997). These procedures have been used for several  
16 decades (Rane *et al.*, 1977), and significant progress has been made in refining the  
17 methods and applying them to a broad range of substrates (Riley *et al.*, 2005; Hallifax *et al.*,  
18 2010). Most of this work has been performed using mammalian (rat, mouse, human)  
19 tissue preparations (liver microsomes, primary hepatocytes, and liver slices). In the last  
20 decade, researchers interested in predicting *in vivo* biotransformation from *in vitro* data  
21 have adapted these methods for use with fish (Nichols *et al.*, 2006).

22 Fish *in vitro* methods have the potential to provide important data for bioaccumulation  
23 assessments, and although many require sacrifice of live animals, may contribute to a  
24 reduction in (or refinement of) animal testing. Approaches for using *in vitro* data to  
25 determine metabolic capacity have been described and studied in several test systems.  
26 [Table R.7.10–6](#) of [Appendix R.7.10-2](#) provides a summary of standardised methods for  
27 use of fish liver S9 fractions and primary cryopreserved hepatocytes (and applicable  
28 extrapolation models), as well as recent publications that evaluated these methods and  
29 used them to predict biotransformation impacts on bioaccumulation. As is evident in this  
30 table, the fish liver S9 and primary hepatocyte (both fresh and cryopreserved) methods  
31 have been well-studied, characterized, and evaluated using a range of test substances.

32 Both the liver S9 and primary hepatocyte assays have been extensively studied and  
33 tested with a range of chemicals. However, it is recognized that more studies are needed  
34 on chemicals with higher log Kow values (>7-8). Additional details and guidance on the  
35 use, application, and domain of applicability of these methods will be discussed in detail  
36 in an OECD Guidance Document that will accompany the two Test Guidelines under  
37 development (OECD Project 3.13).

38 [Table R.7.10–7](#) of [Appendix R.7.10-2](#) provides a summary of other *in vitro* test systems  
39 used to study chemical biotransformation in fish. Included are specifics on the test  
40 substances evaluated and species. The intent of this table is not to provide a  
41 comprehensive list of such studies, but rather to illustrate the range of different test  
42 systems. In most instances, the data obtained from these studies were not used to  
43 predict biotransformation impacts on bioaccumulation, and in general these methods are  
44 not as well-developed as the liver S9 and primary hepatocyte methods. Nevertheless, it

1 may be possible to use one or more of these systems to predict *in vivo* rates of  
2 metabolic clearance, provided that appropriate supporting information is developed  
3 (e.g., extrapolation factors and chemical binding algorithms).

4 The use of *in vitro* data for bioaccumulation assessment requires a strategy for *in vitro-in*  
5 *vivo* extrapolation of measured biotransformation rates and incorporation of estimated  
6 hepatic clearance into appropriate computational models (Nichols *et al.*, 2006). The *in*  
7 *vitro* assays are generally performed using a substrate depletion approach, wherein the  
8 goal is to measure loss of a test substance (parent compound) added to the biological  
9 matrix. This information is then converted to a whole-body biotransformation rate  
10 constant ( $k_{MET}$ ) using several extrapolation factors. When used as an input to a standard  
11 one-compartment model for chemical bioconcentration, the estimated  $k_{MET}$  value is  
12 combined with a first-order rate constant for chemical uptake across the gills ( $k_u$ ) as well  
13 as the summed rate constant for all non-metabolic routes of elimination ( $k_{nb}$ ). The model  
14 may then be used to simulate the chemical concentration in the fish and predict a  
15 steady-state BCF. This approach has been integrated into a published extrapolation  
16 model (Nichols *et al.*, 2013) which was parameterized for small (10 g) rainbow trout  
17 (i.e., representative of those used for *in vivo* OECD TG 305 testing). A standardised  
18 approach for *in vitro* to *in vivo* extrapolation is critical to using and applying *in vitro*  
19 biotransformation rate data for bioaccumulation assessment.

20 Multi-compartment physiologically-based pharmacokinetic models for fish have also been  
21 developed and can be parameterized with *in vitro* biotransformation data for the liver  
22 and other tissues (e.g., gastrointestinal tract, gill). These more complex models may  
23 prove useful for higher tiered bioaccumulation assessments, although additional model  
24 input parameters are required (Nichols *et al.*, 1990; Stadnicka *et al.*, 2012; Stadnicka-  
25 Michalak *et al.*, 2014). Such models may also be appropriate when predicting  
26 biotransformation impacts on chemicals taken up primarily from the diet (Nichols *et al.*,  
27 2007).

28 Standard protocols are available for fish liver S9 fraction isolation and incubations  
29 (Johanning *et al.*, 2012a) and fish liver primary hepatocyte (cryopreserved) isolation and  
30 incubations (Fay *et al.*, 2015a). The development and standardisation of both  
31 methodologies are the result of earlier multi-laboratory ring-trials (Fay *et al.*, 2014a;  
32 Johanning *et al.*, 2012b), and the two methods have been proposed as OECD Test  
33 Guidelines (OECD Project 3.13, OECD 2015). Both the liver S9 and primary  
34 cryopreserved hepatocyte methods are currently undergoing validation through a multi-  
35 laboratory OECD ring-trial (Embry *et al.*, 2015; Fay *et al.*, 2015b). The validation  
36 includes the use of a standard reference chemical (pyrene) for each run, as well as  
37 appropriate negative controls (e.g., heat-treated and no-cofactor samples).

38 A number of the studies shown in [Table R.7.10—6](#) of [Appendix R.7.10-2](#) have collected  
39 *in vitro* metabolism data for fish and performed additional calculations to estimate the  
40 whole-body biotransformation rate constant  $k_{MET}$ . This rate was then used as an input to  
41 predictive models for chemical bioconcentration. To date, this work has shown that  
42 incorporating *in vitro* metabolism data into established bioconcentration models  
43 substantially improves their performance; predicted levels of accumulation are much  
44 closer to measured values than predictions obtained assuming no metabolism (Han *et*  
45 *al.*, 2007, 2009; Cowan-Ellsberry *et al.*, 2008; Dyer *et al.*, 2008; Gomez *et al.*, 2010;  
46 Laue *et al.*, 2014; Fay *et al.*, 2014b).

1 *In vitro* methods employing tissues other than liver, including gill and gastrointestinal  
2 tract are in the earlier stages of development, as are assays using cell lines derived from  
3 these tissues. *In vitro* data from these extrahepatic systems may be of particular  
4 importance when chemicals are metabolised in the gills or gut, or when dietary uptake is  
5 the primary route of exposure. Although these methods have not been used as broadly  
6 as the liver S9 and primary hepatocyte assays, they are promising approaches that could  
7 also address the role of metabolism in bioaccumulation assessment once they are further  
8 developed, standardised, and validated.

9 It should be noted that the presence/absence and activities of different metabolising  
10 enzymes varies among species, and quantitative correlations with fish have not yet been  
11 established. Moreover, the presence of measureable metabolism does not necessarily  
12 correspond to a decrease in risk. Although in general the products of biotransformation  
13 are eliminated more rapidly than the parent compound from which they derive, this is  
14 not always the case. Further, biotransformation may in some cases increase toxicity by  
15 creating reactive metabolites (a process called bioactivation). Technical challenges  
16 associated with *in vitro* measurement of biotransformation include the limited working  
17 lifetime of these preparations and difficulties associated with the use of very hydrophobic  
18 (high log Kow) test substances. Liver spheroids remain viable for long periods of time  
19 and may be particularly well suited for low clearance compounds (Baron *et al.*, 2012),  
20 although this remains to be determined. Alternatively, it may be possible to employ  
21 existing S9 and hepatocyte assays using a relay approach, or some type of hepatic co-  
22 culture system (Di *et al.*, 2012; Hutzler *et al.*, 2015). Lee *et al.* (2012, 2014)  
23 demonstrated the use of a sorbent-phase dosing approach for very hydrophobic  
24 compounds. Research is needed to compare results obtained using this and similar  
25 methods to rates measured using conventional solvent dosing procedures. Additional  
26 work is required to establish the utility and comparability of different *in vitro* systems,  
27 and clarify the role of chemical binding (*in vitro* and *in vivo*) as a determinant of hepatic  
28 clearance.

29 Although *in vitro* data on fish metabolism is not a standard REACH information  
30 requirement, results of such studies can support the bioaccumulation assessment and  
31 can be considered as part of a weight of evidence approach. It should be noted that the  
32 species tested in *in vitro* methods may be different to those used for fish BCF testing.  
33 Currently, further experience is needed in performing *in vitro* fish metabolism studies on  
34 substances with log Kow values >7-8. Whilst such studies may help to explain the  
35 proportion of depuration attributable to metabolism it does not mean that a substance  
36 cannot reach high body burdens.

### 37 Biomimetic techniques

38 Biomimetic extraction systems try to mimic the way organisms extract chemicals from  
39 water. There are three main types:

- 40 • *semi-permeable membrane devices (SPMD)*, which are usually either a bag or  
41 tube made of a permeable membrane (e.g. low density polyethylene) containing  
42 an organic phase (e.g. hexane, natural lipids or the model lipid triolein)  
43 (Södergren, 1987; Huckins *et al.*, 1990). SPMDs have been used to assess  
44 effluents (Södergren, 1987), contaminated waters (Petty *et al.*, 1998) and  
45 sediments (Booij *et al.*, 1998) as animal replacements for assessing potentially  
46 bioaccumulative chemicals.

- 1 • *solid phase micro extraction (SPME)*, consisting of a thin polymer coating on a  
2 fused silica fibre (Arthur and Pawliszyn, 1990). Equilibrium may be achieved in  
3 hours to days, due to the high surface area to volume ratio (Arthur and  
4 Pawliszyn, 1990; Vaes *et al.*, 1996 & 1997).
- 5 • *artificial membranes*, prepared from phospholipids that form small unilamellar  
6 vesicles in water (Gobas *et al.*, 1988; Dulfer and Govers, 1995; Van Wezel *et al.*  
7 1996; Vaes *et al.*, 1997; Vaes *et al.*, 1998a). These vesicles are thought to  
8 resemble the lipid bilayers of natural membranes, and they have mainly been  
9 used to study toxicity (e.g. Vaes *et al.*, 1998b).

10 All three methods will extract only the freely dissolved (i.e. bioavailable) fraction of  
11 chemicals from water samples, in proportion to their partitioning coefficient, which is  
12 mainly related to the hydrophobicity of the substance and molecular size. In this way  
13 they simulate the potential for aquatic organisms to bioconcentrate organic chemicals by  
14 passive diffusion into storage lipids and cell membranes. Both SPMD and SPME are  
15 relatively easy to use. Due to the small size of the organic phase, SPME has a much  
16 shorter equilibration time than SPMD and relatively small sizes of water samples can be  
17 used without depleting the aqueous phase. SPMD is more suitable than SPME to assess  
18 the bioaccumulation potential in the field from prolonged exposure with fluctuating  
19 concentrations of contaminants.

20 Techniques like SPMD and SPME cannot account for metabolism by fish or invertebrates.  
21 It should also be noted that the partition coefficient measured with a particular device  
22 has to be translated to a BCF for organisms using an appropriate conversion factor. For  
23 example, a number of workers have established relationships between SPME partition  
24 coefficients, log  $K_{ow}$  and invertebrate BCFs for a variety of compounds (Verbruggen,  
25 1999; Verbruggen *et al.*, 2000; Leslie *et al.*, 2002).

26 Biomimetic extractions are very useful for measuring the bioavailability of non-  
27 dissociating organic substances in the water phase, or to measure an average exposure  
28 over time in a specific system. However, when interpreting the results from such  
29 methods in the context of bioaccumulation, the following points need to be considered:

- 30 • The data produced are simple measures of substance bioavailability, and  
31 uptake rates will differ from uptake rates in organisms. Equations are needed  
32 to translate between the two. They therefore provide a maximum BCF value  
33 for most substances, linked to the potential passive diffusive uptake into an  
34 organism and distribution into the lipid.
- 35 • They do not simulate the ability of fish to actively transport chemicals, nor  
36 mimic other methods of uptake and storage (e.g. protein binding), which can  
37 be important for some substances. They also neglect mechanisms of  
38 elimination, such as metabolism and excretion.
- 39 • The time to equilibration with water samples can be very long for some types  
40 of device. For example, Booij *et al.* (1998) suggested that results from SPMDs  
41 exposed for less than 2 months should be treated with caution.

42 Bioconcentration can therefore be either overestimated (for readily metabolised and  
43 actively excreted chemicals) or underestimated (e.g. in the case of active uptake of a  
44 substance that is poorly metabolised or when bioaccumulation is not governed by

1 lipophilicity). In addition, since biomimetic methods are only capable of reaching  
 2 equilibrium with freely dissolved chemicals they cannot be used to address the potential  
 3 uptake *via* the gut. They are therefore of limited usefulness in the assessment of  
 4 bioaccumulation.

5

### 6 **R.7.10.3.2 Non-testing data aquatic bioaccumulation**

7 Non-testing data can generally be provided by:

- 8 • Quantitative structure-activity relationships (QSARs);
- 9 • Expert systems; and
- 10 • Grouping approaches (including read-across, structure-activity relationships  
 11 (SARs) and chemical categories).

12 These methods can be used for the assessment of bioaccumulation if they provide  
 13 relevant and reliable data on the chemical of interest.

14

### 15 **(Q)SAR models**

16 **DISCLAIMER: this section does not include the latest information on the use of (Q)SAR**  
 17 **models as it has not been subject of updates since first publication.**

18 (Q)SAR models for predicting fish BCFs have been extensively reviewed in the literature  
 19 (e.g. Boethling and Mackay, 2000; Dearden, 2004; Pavan *et al.*, 2006). ECHA's [Practical](#)  
 20 [Guide 5: How to use and report \(Q\)SARs](#) provides guidance on how to use and report  
 21 (Q)SAR predictions under REACH. The Practical Guide also includes a list of QSAR models  
 22 suitable for predicting bioaccumulation in aquatic species ([Table R.7.10–1](#)):

23

24 **Table R.7.10–1 QSAR models suitable for predicting bioaccumulation in aquatic**  
 25 **species**

| Software tool          | Models/Modules                            | Free or Commercial |
|------------------------|---|--------------------|
| EPI Suite (US EPA)     | BCF BAF                                   | Free               |
| T.E.S.T. (US EPA)      | Bioaccumulation factor                    | Free               |
| VEGA (IRFMN)           | CAESAR, Meylan and KNN/Read-Across models | Free               |
| CASE Ultra (MultiCASE) | EcoTox model bundle                       | Commercial         |
| CATALOGIC (LMC)        | Two BCF base-line models                  | Commercial         |

26

1 The most important approaches for aquatic bioaccumulation (Q)SAR models are  
2 presented below.

3 Some examples are given to illustrate each model type and the techniques used to  
4 develop them. This overview *is not intended to be an exhaustive list of models*: other  
5 methods and models should be considered if relevant. Not all the models were developed  
6 with European regulatory purposes in mind, and so it is important to assess in each case  
7 whether the predicted endpoint corresponds with the regulatory endpoint of interest.

### 8 **BCF models based on log K<sub>ow</sub>**

9 The most common and simplest QSAR models are based on correlations between BCF  
10 and chemical hydrophobicity (as modelled by log K<sub>ow</sub>). The mechanistic basis for this  
11 relationship is the analogy of the partitioning process between lipid-rich tissues and  
12 water to that between *n*-octanol and water (whereby *n*-octanol acts as a lipid surrogate).  
13 In this model, uptake is considered to be a result of passive diffusion through gill  
14 membranes.

15 Several log BCF/log K<sub>ow</sub> relationships for non-polar, hydrophobic organic chemicals have  
16 been proposed and used in the regulatory applications. Some were derived for specific  
17 chemical classes, like chlorinated polycyclic hydrocarbons (Schüürmann *et al.*, 1988) and  
18 anilines (Zok *et al.*, 1991), but several include diverse sets of chemicals (e.g. Neely *et al.*,  
19 1974; Veith *et al.*, 1979; Ellgenhausen *et al.*, 1980; Könemann & van Leeuwen,  
20 1980; Geyer *et al.*, 1982; Mackay, 1982; Veith & Kosian, 1983; Geyer *et al.*, 1984;  
21 Hawker & Connell, 1986; Connell & Hawker, 1988; Geyer *et al.*, 1991; Bintein *et al.*  
22 1993; Gobas, 1993; Lu *et al.*, 1999; Escuder-Gilabert *et al.*, 2001; Dimitrov *et al.*,  
23 2002a). For example, Veith *et al.* (1979) developed the following QSAR for a set of 55  
24 diverse chemicals:

$$25 \log \text{BCF} = 0.85 \times \log K_{ow} - 0.70 \quad R^2 = 0.897, \log K_{ow} \text{ range} = 1-5.5$$

26 where  $R^2$  is the correlation coefficient.

27 The differences between the various correlations are probably due to variations in test  
28 conditions used for the substances in the training sets (Nendza, 1988). The range of log  
29 K<sub>ow</sub> values of the chemicals under study may also be too broad.

30 Linear correlations give a good approximation of the BCF for non-ionic, slowly  
31 metabolised substances with log K<sub>ow</sub> values in the range of 1 to 6. However, the  
32 relationship breaks down with more hydrophobic substances, which have lower BCFs  
33 than would be predicted with such methods. Several possible reasons for this have been  
34 identified (e.g. Gobas *et al.*, 1987; Nendza, 1988; Banerjee and Baughman, 1991),  
35 including:

- 36 • reduced bioavailability and difficulties in measuring exposure concentrations  
37 (due to the low aqueous solubility),
- 38 • failure to reach steady state because of slow membrane passage of large  
39 molecules, and
- 40 • growth dilution, metabolism, degradation, etc.

1 More complicated types of relationship have been developed to overcome this problem.  
2 Hansch (cited in Devillers and Lipnick, 1990) proposed a simple parabolic model; Kubinyi  
3 (1976, 1977 & 1979) and Kubinyi *et al.* (1978) subsequently proposed a bilinear model,  
4 successfully used in many drug design and environmental QSAR studies. Linear,  
5 parabolic and bilinear models were developed and compared by Bintein *et al.* (1983) on  
6 a dataset of 154 diverse chemicals with a log  $K_{ow}$  range from 1.12 to 8.60, highlighting  
7 the better performance of the bilinear relationship:

$$8 \log BCF = (0.910 \times \log K_{ow}) - (1.975 \times \log (6.8E-7 \times K_{ow} + 1)) - 0.786$$

$$9 R^2 = 0.865 \quad s = 0.347 \quad F = 463.51$$

10 Where  $R^2$  is the multiple correlation coefficient,  $s$  is the standard error of the estimate  
11 and  $F$  is the Fisher test value.

12 Connell and Hawker (1988) proposed a 4<sup>th</sup> order polynomial relationship generated in  
13 such a way that the influence of non-equilibrium conditions was eliminated. The curve,  
14 based on data on 43 substances, resembles a parabola with a maximum log BCF value at  
15 a log  $K_{ow}$  of 6.7, and decreasing log BCF values for chemicals with higher log  $K_{ow}$  values.  
16 This relationship was recalculated and recommended for use (as the "modified Connell  
17 equation") in the risk assessment of new and existing chemicals (EC, 2003):

$$18 \log BCF = -0.2 \log K_{ow}^2 + 2.74 \log K_{ow} - 4.72 \quad R^2 = 0.78$$

19 Meylan *et al.* (1999) proposed a suite of log BCF/log  $K_{ow}$  models based on a fragment  
20 approach from the analysis of a large data set of 694 chemicals. Measured BCFs and  
21 other experimental details were collected in the Syracuse BCFWIN database (SRC  
22 Bioconcentration Factor Data Base) and used to support the BCFWIN software (Syracuse  
23 Research Corporation, Bioconcentration Factor Program BCFWIN). Chemicals with  
24 significant deviations from the line of best fit were analysed carefully dividing them into  
25 subsets of data on non-ionic, ionic, aromatic and azo compounds, tin and mercury  
26 compounds. Because of the deviation from rectilinearity, different models were  
27 developed for different log  $K_{ow}$  ranges, and a set of 12 correction factors and rules were  
28 introduced to improve the accuracy of the BCF predictions. On average, the goodness of  
29 fit of the derived methodology is within one-half log unit for the compounds under study.

30 A single non-linear empirical model between log BCF and log  $K_{ow}$  was derived by  
31 Dimitrov *et al.* (2002a) for 443 polar and non-polar narcotic chemicals with log  $K_{ow}$  range  
32 from -5 to 15 extracted from the Meylan *et al.* (1999) data set. Hydrophobicity was  
33 found to explain more than 70% of the variation of the bioconcentration potential. A  
34 linear relationship was identified in the range for log  $K_{ow}$  1 to 6. The compounds were  
35 widely dispersed around and beyond the maximum of the log BCF/log  $K_{ow}$  curve. This  
36 QSAR gives a Gaussian-type correlation to account for the log BCF approximating to 0.5  
37 at low and high log  $K_{ow}$  values. The continuous aspect of the proposed model was  
38 considered more realistic than the broken line model of Meylan *et al.* (1999). The main  
39 originality of this model, compared to other non-linear QSARs, is its asymptotic trend for  
40 extremely hydrophilic and hydrophobic chemicals.

41 Overall, it can be concluded that:

- 42 • linear equations are applicable in the log  $K_{ow}$  range of 1-6; and

- 1           • non-linear equations show better performance above a log  $K_{ow}$  of 6.  
2 A log  $K_{ow}$  of 6 can therefore be used as the switch point between the two types, based on  
3 the fact they cross at a log  $K_{ow}$  value just above 6.

#### 4 **BCF models based on other experimentally derived descriptors**

5 Although not as extensively used as log  $K_{ow}$ , correlations of BCF with aqueous solubility  
6 (S) have been developed (e.g. Chiou *et al.*, 1977; Kenaga & Goring, 1980; Davies &  
7 Dobbs, 1984; Jørgensen *et al.*, 1998). It should be noted that a strong (inverse)  
8 relationship exists between log  $K_{ow}$  and aqueous solubility for liquids. However, aqueous  
9 solubility is not a good estimate of hydrophobicity for solids (since the melting point also  
10 has an influence), and instead the solubility of the supercooled liquid should be used (if  
11 this can be estimated, e.g. see Yalkowski *et al.*, 1979).

12 As an example, Isnard and Lambert (1988) developed the following BCF model for 107  
13 chemicals (both solids and liquids) where aqueous solubility is in mol/m<sup>3</sup>:

14  $\log \text{BCF} = -0.47 \times \log S + 2.02 \quad R^2 = 0.76$

15 It should be noted that both the slope and regression correlation coefficient are relatively  
16 low. This is a common problem for such QSARs that include both solids and liquids in  
17 their training set. Predictions may therefore be prone to significant error. Consequently,  
18 specific justification should be made for applying QSARs based on aqueous solubility.

#### 19 **BCF models based on theoretical molecular descriptors**

20 The mechanistic basis of the majority of BCF QSAR models based on either log  $K_{ow}$  or  
21 aqueous solubility was determined prior to modelling by ensuring that the initial set of  
22 training structures and/or descriptors were selected to fit a pre-defined mechanism of  
23 action. However, the empirical input parameter data might not always be available for  
24 every substance (e.g. there may be technical difficulties in performing a test), or the  
25 substance could be outside the domain of predictive models. Consequently, other models  
26 have been proposed in the literature following statistical studies based on theoretical  
27 descriptors. Examples include methods based on:

- 28           • **molecular connectivity indices** (MCI) (Sabljic & Protic, 1982; Sabljic,  
29 1987; Lu *et al.*, 1999; Lu *et al.*, 2000),  
30           • solvatochromic or linear solvation energy relationship (LSER) descriptors  
31 (Kamlet *et al.*, 1983; Park & Lee, 1983),  
32           • **fragment constants**, based on chemical fragmentation according to rules  
33 developed by Leo (1975) (Tao *et al.*, 2000 & 2001; Hu *et al.*, 2005),  
34           • quantum chemical descriptors (Wei *et al.*, 2001), and  
35           • **diverse theoretical molecular descriptors** selected by genetic algorithm  
36 (Gramatica and Papa, 2003 & 2005).

37 Theoretical descriptors do not suffer from variability, but are difficult to determine by the  
38 non-expert. In addition, such models are perceived by the developers to be capable of  
39 providing predictions for a wider set of chemicals than is normally the case. However,  
40 whilst the domain of these types of model is occasionally well described, most require a

1 certain degree of competence to determine whether the training set of the model is  
2 relevant for the chemical of interest. Since the mechanistic basis of these models is  
3 determined post-modelling, by interpretation of the final set of training structures and/or  
4 descriptors, they are often criticised for their lack of mechanistic interpretability. The use  
5 of this type of model should therefore be thoroughly described and justified if a  
6 registrant chooses to predict a BCF this way.

### 7 **QSAR model for identifying “B-profile”**

8 A base-line modelling concept was proposed by Dimitrov *et al.* (2005a), specifically for  
9 PBT assessment. It is based on the assumption of a maximum bioconcentration factor  
10 ( $BCF_{max}$ ) (Dimitrov *et al.*, 2003) with a set of mitigating factors used to reduce this  
11 maximum, such as molecular size, maximum diameter (Dimitrov *et al.*, 2002b),  
12 ionisation and potential metabolism by fish (as extrapolated from rodent metabolic  
13 pathways). Substances in the training set were divided into groups based on log  $K_{ow}$   
14 intervals of 0.5, and the five highest BCFs in each group were used to fit a curve of  
15 maximum uptake (via passive diffusion). The model therefore predicts a maximum BCF  
16 ( $BCF_{max}$ ) for a substance, which may be higher than BCFs estimated using other  
17 techniques, especially for small non-ionised poorly metabolised substances.

18 For the training set used, the most important mitigating factor to obtain a predicted BCF  
19 closest to the actual measured BCF was metabolism. The derived model was  
20 demonstrated to perform very well in terms of sensitivity and specificity. In addition, the  
21 measured BCF data used for the training set are provided together with a general  
22 description of the applicability domain of the model.

### 23 **Food web bioaccumulation models**

24 While many QSARs have been proposed to model the BCF, fewer models are available  
25 for the bioaccumulation factor (BAF) (e.g. Barber *et al.*, 1991; Thomann *et al.*, 1992;  
26 Gobas, 1993; Campfens & Mackay, 1997; Morrison *et al.*, 1997).

27 Food chain or food web models can be used to predict bioaccumulation in aquatic (and  
28 terrestrial) organisms (Hendriks & Heikens, 2001; Traas *et al.*, 2004) as well as humans  
29 (e.g. Kelly *et al.*, 2004). These models integrate uptake from water, air and dietary  
30 sources such as detritus (water or sediment), plants or animals. Concentrations in  
31 organisms in a food chain can be modelled by linking a set of equations for each trophic  
32 level to describe uptake from water and consecutive food sources.

33 If species have several dietary sources, a more complex food web exists where fluxes  
34 between different species can occur simultaneously. Such a model is mathematically  
35 very similar to multimedia models to describe environmental fate. The great advantage  
36 of these models is that food webs of any dimension can be described, with as many food  
37 sources as needed, and concentrations in all species can be calculated simultaneously  
38 (Sharpe & Mackay, 2000).

39 In general, food web models successfully predict steady-state concentrations of  
40 persistent halogenated organic pollutants which are slowly metabolised (Arnot & Gobas,  
41 2004; Traas *et al.*, 2004). However, these mass-balance models are often  
42 computationally intensive and typically require site-specific information, so are not  
43 readily applicable to screen large numbers of chemicals.

1 A different, simpler approach can be taken by estimating the BAF of species at different  
2 trophic levels that account for both water and food uptake with empirical regressions  
3 (Voutsas *et al.*, 2002) or a semi-empirical BAF model (Arnot and Gobas, 2003). These  
4 are calibrated on measured field BAF data and calculate a maximum BAF for organic  
5 chemicals in selected generic trophic levels (algae, invertebrates and fish). The Arnot  
6 and Gobas (2003) food web bioaccumulation model is a simple, single mass-balance  
7 equation that has been used extensively by Environment Canada for categorising organic  
8 substances on the Canadian Domestic Substances List. The model requires few input  
9 parameters (i.e. only  $K_{ow}$  and metabolic transformation rate, if available – the default is  
10 zero), and derives the BAF as the ratio of the chemical concentration in an upper trophic  
11 level organism and the total chemical concentration in unfiltered water (it also estimates  
12 an overall biomagnification factor for the food web). It accounts for the rates of chemical  
13 uptake and elimination (a number of simple relationships have been developed to  
14 estimate the rate constants for organic chemicals in fish from Gobas, 1993), and  
15 specifically includes bioavailability considerations.

16 The main discrepancies between model predictions and measured BAF values are often  
17 due to biotransformation of a chemical by the organism and to an overestimation of  
18 bioavailable concentrations in the water column and sediment. Other important sources  
19 of discrepancies relate to differences in site-specific food chain parameters versus  
20 generic assumptions (e.g. growth rates, lipid contents, food chain structure, spatial and  
21 temporal variation in exposure concentrations, sediment-water disequilibrium, etc.).

## 22 **Read-across and categories**

23 See also Sections R.6.1 and R.6.2.

24 If a substance belongs to a class of chemicals that are known to accumulate in living  
25 organisms, it may have a potential to bioaccumulate. If a valid BCF for a structurally  
26 closely related substance is available, read-across can be applied. When applying read-  
27 across two important aspects have to be considered, i.e. the lipophilicity and the centre  
28 of metabolic action for both substances (see Section [R.7.10.4.2](#)).

29

### 30 **R.7.10.3.3 Field data on aquatic bioaccumulation**

31 Although interpretation is often difficult, the results of field measurements can be used  
32 to support the assessment of risks due to secondary poisoning (Ma, 1994), and the PBT  
33 assessment. The following study types can provide information on bioaccumulation  
34 properties of substances:

- 35 • **Monitoring data:** Detection of a substance in the tissue of an organism  
36 provides a clear indication that it has been taken up by that organism, but  
37 does not by itself indicate that significant bioconcentration or bioaccumulation  
38 has occurred. For that, the sources and contemporary exposure levels (for  
39 example through water as well as food) must be known or reasonably  
40 estimated.
- 41 • **Field measurements of specific food chains/webs:** Measurement of  
42 concentrations in organisms at various trophic levels in defined food chains or  
43 food webs can be used to evaluate biomagnification. However, as dietary and

1 trophic biomagnification represent different processes than bioconcentration in  
2 aquatic organisms, BMF and/or TMF values <1 cannot be directly used to  
3 disregard valid BCF data > 2000 or BCF > 5000, but these data are separate  
4 lines of evidence and need to be considered together with other relevant  
5 available data in a *weight-of-evidence approach* for deriving conclusions.

- 6 • **Outdoor mesocosms:** Outdoor meso- or microcosm studies can be  
7 performed with artificial tanks or ponds or by enclosing parts of existing  
8 ecosystems (guidance is provided in OECD, 2006). Although the focus of such  
9 studies is usually on environmental effects, they can provide information on  
10 bioaccumulation in the system provided adequate measurements of  
11 concentration are made.

- 12 • ***In situ* bioaccumulation tests using caged organisms:** Sibley *et al.*  
13 (1999) constructed a simple, inexpensive bioassay chamber for testing  
14 sediment toxicity and bioaccumulation under field conditions using the midge  
15 *Chironomus tentans* and the oligochaete *Lumbriculus variegatus*. They  
16 concluded that the *in situ* bioassay could be used successfully to assess  
17 bioaccumulation in contaminated sediments. These studies can bypass  
18 problems caused by sediment manipulation during collection for laboratory  
19 tests (disruption of the physical integrity of a sediment can change the  
20 bioavailability of contaminants). Organisms in *in situ* tests are exposed to  
21 contaminants via water and/or food. The tests cannot make a distinction  
22 between these routes. Also, environmental factors potentially modifying the  
23 bioaccumulation process are not controlled. These factors include (but are not  
24 limited to) lack of knowledge or control of exposure concentrations and  
25 bioavailability aspects. Temperature or water oxygen content may also impact  
26 the physiological status of the organism, and consequently influence the  
27 uptake rate.

28 Field studies can be used to derive bioaccumulation factors (BAFs) and biota-sediment  
29 accumulation factors (BSAFs), and have been used to develop water quality standards  
30 (e.g. US-EPA, 2000b). B(S)AFs are simple ratios - neither definition includes any  
31 statement about ecosystem conditions, intake routes and relationships between the  
32 concentrations of substances in the organism and exposure media (see Ankley *et al.*,  
33 1992; Thomann *et al.*, 1992). Field B(S)AF values are affected by ecosystem variables  
34 like the natural temporal and spatial variability in exposure, sediment-water column  
35 chemical relationships, changing temperatures, simultaneous exposure to mixtures of  
36 chemicals and nutrients, and variable exposures due to past and current loadings. In  
37 general, data obtained under (pseudo-)steady-state conditions are strongly preferred.

38 It should also be noted that substantial variation can be found both within and between  
39 studies reporting field-derived BAFs for zooplankton (Borgå *et al.*, 2005), and this  
40 variability should not be overlooked when relating BAFs to  $K_{ow}$  or other descriptors. The  
41 authors attribute the variability to difficulties with measurements of the substance in the  
42 water phase, additional dietary uptake and the possibility that substances partition into  
43 other organic phases than lipids.

44 The quantity and quality of field data may be limited and their interpretation difficult.  
45 This is especially true for trophic magnification factors, which describe the accumulation  
46 throughout the whole food chain. The validity of the TMF is strongly dependent on the

1 spatial and time scales over which the samples are retrieved. This is discussed further in  
2 Section R.11.4.1.2 in Chapter R.11 of the [Guidance on IR&CSA](#).

3

#### 4 **R.7.10.3.4 Other indications of bioaccumulation potential**

5 The following factors will be relevant for many substances as part of a *Weight-of-*  
6 *Evidence* approach, especially in the absence of a fully valid fish BCF test result.

##### 7 **n-Octanol/water partition coefficient**

8 As a screening approach, the potential for bioaccumulation can be estimated from the  
9 value of the n-octanol/water partition coefficient ( $K_{ow}$ ) (see Section R.7.1 in Chapter R.7a  
10 of the [Guidance on IR&CSA](#)). It is accepted that  $\log K_{ow}$  values greater than or equal to 3  
11 indicate that the substance may bioaccumulate to a significant degree. For certain types  
12 of chemicals (e.g. surface-active agents and those which ionise in water), the  $\log K_{ow}$   
13 might not be suitable for calculation of a BCF value (see [Appendix R.7.10-3](#)). There are,  
14 however, a number of factors that are not taken into consideration when the BCF is  
15 estimated only on the basis of  $\log K_{ow}$ , namely:

- 16 • active transport phenomena;
- 17 • metabolism in organisms and the accumulation potential of any metabolites;
- 18 • affinity due to specific interactions with tissue components;
- 19 • special structural properties (e.g. amphiphilic substances or dissociating  
20 substances that may lead to multiple equilibrium processes); and
- 21 • uptake and depuration kinetics (leading for instance to a remaining  
22 concentration plateau in the organism after depuration).

23 In addition, n-octanol only simulates the lipid fraction and therefore does not simulate  
24 other storage sites (e.g. protein).

25 It should be noted that although  $\log K_{ow}$  values above about eight can be calculated,  
26 they can not usually be measured reliably (see Section R.7.1 in Chapter R.7a of the  
27 [Guidance on IR&CSA](#)). Such values should therefore be considered in qualitative terms  
28 only. It has also been assessed whether an upper  $\log K_{ow}$  limit value should be  
29 introduced based on the lack of experimental  $\log K_{ow}$  and BCF values above such a value.  
30 Based on current knowledge, for PBT assessments, a calculated  $\log K_{ow}$  of 10 or above is  
31 taken as an indicator of reduced bioconcentration. The use of this and other such  
32 indicators (such as high molecular mass and large molecular size) is discussed further in  
33 Chapter R.11 of the [Guidance on IR&CSA](#).

##### 34 **Adsorption**

35 Adsorption onto biological surfaces, such as gills or skin, may also lead to  
36 bioaccumulation and an uptake via the food chain. Hence, high adsorptive properties  
37 may indicate a potential for both bioaccumulation and biomagnification. For certain  
38 chemicals, for which the octanol/water partition coefficient cannot be measured properly,

1 a high adsorptive capacity (of which  $\log K_p > 3$  may be an indication) can be additional  
2 evidence of bioaccumulation potential.

### 3 **Hydrolysis and other abiotic degradation/transformation phenomena** 4 **taking place in the exposure medium**

5 The effect of hydrolysis may be a significant factor for substances discharged mainly to  
6 the aquatic environment: if the substance is sufficiently hydrophilic, its concentration in  
7 water may be reduced by hydrolysis so the extent of bioconcentration in aquatic  
8 organisms would also be reduced. However, for substances which are highly adsorptive  
9 to organic matter and/or lipids, the adsorption rate is, in most cases, faster than the  
10 hydrolysis rate. Therefore, hydrolysis rate should normally not intervene with  
11 assessment of bioaccumulation potential. In case a substance has a fast hydrolysis rate,  
12 the degradation potential of the substance in sediment and/or soil needs to be  
13 evaluated/tested first and if the substance is stable enough in water and/or soil from the  
14 perspective of quantitative risk assessment and/or PBT/vPvB assessment, the  
15 bioaccumulation potential of the substance itself needs to be evaluated/tested in  
16 conditions ensuring a stable exposure concentration despite fast hydrolysis. Where the  
17 hydrolysis half-life, at environmentally relevant pH values (4-9) and temperature, is less  
18 than 12 hours, and in cases where the above-described scenario does not apply, it may  
19 be appropriate to perform an exposure assessment, a hazard assessment and, if  
20 necessary, a bioaccumulation test on the relevant hydrolysis products instead of the  
21 parent substance. It should be noted that, in many cases, hydrolysis products are more  
22 hydrophilic and as a consequence will have a lower potential for bioaccumulation than  
23 the (registered) substance itself. This also applies by analogy to other abiotic  
24 degradation and transformation routes, such as complex dissolution/transformation  
25 processes.

### 26 **Biodegradation**

27 Biodegradation may lead to relatively low concentrations of a substance in the aquatic  
28 environment and thus to low concentrations in aquatic organisms. In addition, readily  
29 biodegradable substances are likely to be rapidly metabolised in organisms. However,  
30 the uptake rate may still be greater than the rate of the degradation processes, leading  
31 to high BCF values even for readily biodegradable substances. Therefore ready  
32 biodegradability does not preclude a bioaccumulation potential. The ultimate  
33 concentration in biota (and hence bioaccumulation factors) will depend also on  
34 environmental releases and dissipation, and also on the uptake and metabolism and  
35 depuration rate of the organism. Readily biodegradable chemicals will generally have a  
36 higher probability of being metabolised in exposed organisms to a significant extent than  
37 less biodegradable chemicals. Thus in general terms (depending on exposure and  
38 uptake), concentrations of most readily biodegradable substances will be low in aquatic  
39 organisms and evidence of ready biodegradability may provide useful information in a  
40 *Weight-of-Evidence* approach for bioaccumulation assessment. Information on  
41 degradation kinetics will usually be missing for most substances.

42 If persistent metabolites are formed in substantial amounts the bioaccumulation  
43 potential of these substances should also be assessed. However, for most substances  
44 information will be scarce (see Section R.7.9 in Chapter R.7b of the of the [Guidance on](#)  
45 [IR&CSA](#)). Information on possible formation of degradation products may also be

1 obtained by use of expert systems such as METABOL and CATABOL which can predict  
2 biodegradation pathways and metabolites (see Section R.7.9 in Chapter R.7b of the of  
3 the [Guidance on IR&CSA](#)). Information on the formation of metabolites may be obtained  
4 from experiments with mammals, although extrapolation of results should be treated  
5 with care, because the correlation between mammalian metabolism and environmental  
6 transformation is not straightforward (see below). Predictions of possible metabolites in  
7 mammalian species (primarily rodents) may be obtained by use of expert systems such  
8 as Multicase and DEREK (see Sections R.7.9.6 in Chapter R.7b and R.6.1 in Chapter R.6  
9 of the [Guidance on IR&CSA](#)), offering predictions of metabolic pathways and metabolites  
10 as well as their biological significance.

11 Interpretation of expert systems predicting formation of possible degradation products or  
12 metabolites like those referred to above require expert judgement. This applies for  
13 example in relation to identification of the likelihood and possible biological significance  
14 of the predicted transformation products, even though some of the systems do offer  
15 some information or guidance in this regard.

## 16 **Molecular size**

17 Information on molecular size can be an indicator to strengthen the evidence for a  
18 limited bioaccumulation potential of a substance. See Chapter R.11 of the [Guidance on](#)  
19 [IR&CSA](#) for further discussion.

## 20 **Additional considerations**

21 For air-breathing organisms, respiratory elimination occurs via lipid-air exchange, and  
22 such exchange declines as the octanol-air partition coefficient ( $K_{oa}$ ) increases, with  
23 biomagnification predicted to occur in many mammals at a log  $K_{oa}$  above 5 (Kelly *et al.*,  
24 2004). Such biomagnification does not occur if the substance and its metabolites are  
25 rapidly eliminated in urine (i.e. have a log  $K_{ow}$  of around 2 or less). Thus the  
26 bioaccumulation potential in air-breathing organisms is a function of both log  $K_{ow}$  and log  
27  $K_{oa}$ . In contrast, respiratory elimination in non-mammalian aquatic organisms occurs via  
28 gill ventilation to water, and this process is known to be inversely related to the log  $K_{ow}$   
29 (hence an increase in log  $K_{ow}$  results in a decrease in the rate of elimination and hence  
30 increase in the accumulation potential)(Gobas *et al.* (2003)).

31 Based on these findings, Kelly *et al.* (2004) proposed that chemicals could be classified  
32 into four groups based on their potential to bioaccumulate in air-breathing organisms.  
33 These groups are summarised below.

- 34 • Polar volatiles (low log  $K_{ow}$  and low log  $K_{oa}$ ). These substances have low  
35 potential for bioaccumulation in air-breathing organisms or aquatic organisms.
- 36 • Non-polar volatiles (high log  $K_{ow}$  and low log  $K_{oa}$ ). These substances are  
37 predicted to have a high accumulation potential in aquatic organisms but a  
38 low accumulation potential in air-breathing mammals.
- 39 • Non-polar non-volatiles (high log  $K_{ow}$  and high log  $K_{oa}$ ). These substances  
40 have a high bioaccumulation potential in both air-breathing organisms and  
41 aquatic organisms.

- 1           • Polar non-volatiles (low log  $K_{ow}$  and high log  $K_{oa}$ ). This group of substances  
2           has a low bioaccumulation potential in aquatic organisms but a high  
3           bioaccumulation potential in air-breathing organisms (unless they are rapidly  
4           metabolised).

5 These findings may be a relevant consideration for accumulation in top predators for  
6 some chemicals whose bioaccumulation potential in aquatic systems appears to be  
7 limited.

###### 13 Fish bioconcentration test

14 In principle, studies that have been performed using standard test guidelines should  
15 provide fully valid data, provided that:

- 16           • the test substance properties lie within the recommended range stipulated by  
17           the test guideline,
- 18           • concentrations are quantified with an appropriate analytical technique, and
- 19           • the data are reported in sufficient detail to verify that the validity criteria are  
20           fulfilled.

21 The results should be presented in unambiguously specified units as well as tissue type  
22 (e.g. whole body, muscle, fillet, liver, fat). Whole body measurements are preferred and  
23 the correction for fat content and growth dilution is recommended (see section below on  
24 correction factors).

25 Detailed guidance on interpretation of fish bioaccumulation test data is provided in OECD  
26 (2001) and OECD (2012a). Further guidance is also now available (Parkerton *et al.*,  
27 2008) following a workshop sponsored by the International Life Sciences Institute (ILSI)-  
28 Health & Environmental Sciences Institute (HESI). This addressed key evaluation criteria  
29 based on past literature reviews (e.g. Barron, 1990) and recently proposed evaluation  
30 criteria for bioaccumulation and bioconcentration data (Arnot & Gobas, 2003). Finally,  
31 the CEFIC-LRI project to develop a gold standard database has also produced a report  
32 on how to assess the quality of a BCF study (Versonnen *et al.*, 2006). The following brief  
33 guidelines are based on these various documents. A checklist is also presented in  
34 [Appendix R.7.10-4](#).

###### 35 Test substance information

- 36           • The identity of the test substance must be specified, including the chemical  
37           name, CAS number and purity (the latter particularly for radiolabelled test  
38           substances).

- 1           • Key physico-chemical properties (e.g. water solubility and  $K_{ow}$ ) need to be  
2 considered in assessing data quality. The water solubility can be used to  
3 evaluate whether the dissolved chemical concentration available to the  
4 organism may have been overestimated, leading to an underestimate of the  
5 BCF. The  $K_{ow}$  value can provide an indication of whether sufficient exposure  
6 time has been provided for achieving steady-state conditions (in small fish for  
7 non-polar organic chemicals assuming worst case conditions, i.e. no  
8 metabolism) (see OECD (1996) for further details).

9 Test species information

- 10           • The test species must be identified, and ideally, test organisms should be of a  
11 specified gender, life stage and age/size (since these may account for  
12 differences in metabolic transformation potential or growth). A steady-state  
13 condition is reached faster in smaller organisms than in larger ones due to  
14 their higher respiratory surface-to-weight ratio. Fish size is therefore an  
15 important consideration for assessing whether the exposure duration is  
16 sufficient.
- 17           • Whole body lipid content is also a key organism parameter (although this is  
18 sometimes not reported), since this variable controls the degree of  
19 partitioning between the water and the organism for many organic chemicals  
20 (see *correction factors*, below).

21 Analytical measurements

- 22           • Studies that involve only nominal exposure concentrations are unreliable  
23 unless adequate evidence is available from other studies to suggest that  
24 concentrations would have been well maintained.
- 25           • A reliable study should use a parent substance-specific analytical method in  
26 both exposure medium and fish tissue. Studies that describe the use of  
27 accepted and sensitive substance-specific methods but fail to document (or  
28 give further reference to) analytical method validation (e.g. linearity,  
29 precision, accuracy, recoveries and blanks) should be assessed on a case-by-  
30 case – they might best be designated as *reliable with restrictions*. Studies that  
31 do not describe the analytical methods should be designated as not  
32 assignable, even if they are claimed to provide substance-specific  
33 measurements.
- 34           • Radiolabelled test substance can be useful to detect organ specific enrichment  
35 or in cases where there are analytical difficulties. However, total radioactivity  
36 measurements alone can lead to an overestimation of the parent substance  
37 concentration due to:
- 38           • small amounts of radiolabelled impurities that may be present in the test  
39 substance, and/or
- 40           • biodegradation and biotransformation processes in the exposure medium and  
41 fish tissue (i.e. the measurements may relate to parent substance plus  
42 metabolites (if the radiolabel is placed in a stable part of the molecule) and  
43 even carbon that has been incorporated in the fish tissue).

1 A parent compound-specific chemical analytical technique or selective clean-  
2 up procedure should therefore preferably be used at the end of the exposure  
3 period. If the parent substance is stable in water and an enrichment of  
4 impurities is not likely from the preparation of the test solution, the BCF based  
5 on total radioactivity alone can generally be considered a conservative value.  
6 It is also important to evaluate the feeding regime as well, since high  
7 concentrations of (usually more polar) metabolites may build up in the gall  
8 bladder if the fish are not fed, which may lead to an overestimate of whole  
9 body levels (OECD, 2001). For example, Jimenez *et al.* (1987) measured a  
10 BCF of 608 for benzo[*a*]pyrene (based on total radioactivity) when fish were  
11 fed during the experiment, but a BCF of 3,208 when they were not. Decreased  
12 respiration and metabolism as well as a decreased release of bile from the gall  
13 bladder in the intestinal tract are mentioned as possible explanations.

- 14 • If the solubility of a substance is recorded as less than the analytical detection  
15 limit, the bioconcentration potential should be based on the log  $K_{ow}$  if a  
16 reliable estimate of water solubility cannot be derived (OECD, 2001).

#### 17 Exposure conditions

- 18 • Exposure concentrations should not exceed the aqueous solubility of the test  
19 substance. In cases where test exposures significantly exceed aqueous  
20 solubility (e.g. due to the use of dispersants), and the analytical method does  
21 not distinguish between dissolved and non-dissolved substance, the study  
22 data should generally be considered unreliable. An indication of the BCF might  
23 be given by assuming that the organisms were exposed at the water solubility  
24 limit.
- 25 • Aqueous exposure concentrations must be below concentrations that pose a  
26 toxicity concern. Typically, the highest exposure concentration should be less  
27 than 10% of the TLM (Median Threshold Limit) at 96h, and the lower  
28 concentration should be at least 10 times higher than its detection limit in  
29 water according to OECD TG 305 (OECD, 1996).
- 30 • Aqueous exposure concentrations should be kept relatively constant during  
31 the uptake phase. In the case of the OECD test guideline, the concentration of  
32 test substance in the exposure chambers must be maintained within  $\pm 20\%$  of  
33 the mean measured value. In the case of the ASTM guideline, the highest  
34 measured concentration should be no greater than a factor of two from the  
35 lowest measured concentration in the exposure chamber.

#### 36 Other test conditions

- 37 • While criteria vary, fish mortality less than 10-20% in treated and control  
38 groups is generally acceptable. In cases where  $>30\%$  mortality is reported,  
39 the study should be considered not reliable. If no mortality information is  
40 provided, one option is to designate the study as 'reliable with restrictions' if  
41 the exposure concentration used is at least a factor of 10 below the known or  
42 predicted fish  $LC_{50}$ .
- 43 • Standard guidelines require  $>60\%$  oxygen saturation to be maintained in test  
44 chambers throughout the study. It is suggested that as long as unacceptable

1 mortality does not occur, studies that deviate in this requirement could also  
2 be considered *reliable with restrictions*.

- 3 • Total organic carbon (TOC) in dilution water is also an important water quality  
4 parameter for some substances (especially for highly hydrophobic  
5 substances), since excess organic colloids can complex the test substance and  
6 reduce the bioavailability of aqueous exposure concentrations (e.g. Muir *et al.*,  
7 1994). OECD and ASTM guidelines indicate that TOC should be below 2 and 5  
8 mg/l, respectively. It is, therefore, suggested that studies with such  
9 substances that report TOC above 5 mg/l be considered not reliable (since this  
10 can result in an underestimation of the BCF). If no information is available on  
11 TOC, a study may be considered reliable with restriction provided that it was  
12 conducted under flow-through conditions and that analysis of the substance  
13 was for the dissolved concentration. Further support for reliability may be  
14 provided where information on TOC can be derived from other sources (e.g.  
15 where the test water is from a natural source that is characterised elsewhere).
- 16 • The test endpoint should reflect steady-state conditions. The steady-state BCF  
17 may be obtained using the *plateau method* (see OECD, 1996; i.e. mean fish  
18 concentrations are not significantly different between three sequential  
19 sampling points during the uptake phase). Alternatively, the BCF is derived  
20 using kinetic models. If neither of these approaches is used, the study should  
21 be considered unreliable (or at best reliable with restrictions) unless a case  
22 can be made that the exposure duration was sufficiently long to provide or  
23 allow correction to reflect steady-state conditions.

#### 24 Steady-state vs kinetic BCF

25 The kinetic BCF ( $BCF_K$ ) is preferred for regulatory purposes since for bioaccumulative  
26 substances a real steady state is often not attained during the uptake phase, and the  
27 conclusion of steady-state from the concentrations in fish at three consecutive time  
28 points could be erroneous.

29 This approach is especially useful in those cases in which steady-state is not reached  
30 during the uptake phase, as  $BCF_K$  in these cases will generally provide a statistically  
31 more robust value. If uptake follows first order kinetics and the  $BCF_{SS}$  was really based  
32 on steady state data, both methods should in principle lead to the same result. If the  
33  $BCF_K$  is significantly different from the  $BCF_{SS}$ , this is a clear indication that steady-state  
34 has not been attained in the uptake phase. Besides that, the  $BCF_{SS}$  cannot be corrected  
35 for the growth of fish as no agreed method is available to correct  $BCF_{SS}$  for growth. The  
36 increase in fish mass during the test will result in a decrease of the test substance  
37 concentration in growing fish (= growth dilution) and thus the BCF may be  
38 underestimated if no correction is made. Growth dilution may affect both  $BCF_{SS}$  and  
39  $BCF_K$  and therefore the  $BCF_K$  should be calculated and corrected for growth dilution,  
40  $BCF_{kg}$ , if growth of fish is significant during the test (this is especially important for fast  
41 growing juvenile fish, such as juvenile rainbow trout). In case the uptake and/or  
42 elimination phases appear as non-first order/biphasic, specific attention should be paid  
43 to whether the results can be considered as reliable and/or whether, on a case-by-case  
44 basis, any part(s) of the test results can still be used for chemical safety assessment or  
45 whether a new test should be carried out.

## 1 Correction factors

2 The accumulation of hydrophobic substances is often strongly influenced by the lipid  
3 content of the organism. Fish lipid content varies according to species, season, location  
4 and age, and it can range from around 0.5 to 20% w/w or more in the wild (e.g.  
5 Hendriks & Pieters, 1993). Normalisation to lipid content is therefore one way to reduce  
6 variability<sup>4</sup> when comparing measured BCFs for different species, or converting BCF  
7 values for specific organs to whole body BCFs, or for higher tier modelling.

8 The first step is to calculate the BCF on a per cent lipid basis using the relative fat  
9 content in the fish, and then to calculate the whole body BCF for a fish assuming a fixed  
10 whole body lipid content. However, if the lipid content of individual fish are reported or  
11 lipid contents are reported for several phases of the study, it is more appropriate to  
12 perform the lipid normalization to the default lipid content before a BCF is calculated  
13 (e.g. the steady state or kinetic parameters are determined from the normalized data).

14 A default value of 5% is most commonly used as this represents the average lipid  
15 content of the small fish used in OECD TG 305 (Pedersen *et al.*, 1995; Tolls *et al.*, 2000).  
16 Generally, the highest valid wet weight BCF value expressed on this default lipid basis is  
17 used for the hazard and risk assessment. In cases where BCFs are specified on tissue  
18 types other than whole body (e.g. liver), the results cannot be used unless tissue-  
19 specific BCF values can be normalised to lipid content and converted to a whole body  
20 BCF based on pharmacokinetic considerations.

21 Lipid normalisation should be done where data are available, except for cases where lipid  
22 is not the main compartment of accumulation (e.g. inorganic substances, certain  
23 perfluorinated compounds, etc.). Both OECD TG 305 and ASTM E1022-94 require  
24 determination of the lipid content in the test fish used. If fish lipid content data are not  
25 provided in the test report, relevant information may be available separately (e.g. in the  
26 test guideline or other literature although this bears considerable uncertainty with it,  
27 because lipid contents can vary for the selected species and even between individuals of  
28 the same from the same laboratory). If no information is available about the fish lipid  
29 content, the BCF has to be used directly based on available wet weight data, recognising  
30 the large uncertainty this implies.

31 It should be noted that QSARs generally predict BCFs on a wet weight basis only. An  
32 exception to this is the Arnot-Gobas method included in BCFBAF of EPIWIN, which  
33 specifically calculates BAFs for different trophic levels and BCFs, where relevant (lipid  
34 content 10.7%, 6.85% and 5.98% for the upper, middle and lower trophic level,  
35 respectively). When using results from this model, there also is need to normalise the  
36 results to the standard 5% lipid content. Further work would be needed to determine  
37 whether any lipid correction is necessary for predicted values with other QSARs.

---

<sup>4</sup> Some residual variation will remain due to the way the lipid is extracted (e.g. extraction using chloroform gives different amounts for aliquots from the same sample than if hexane were used as the solvent) and measured (e.g. colometric versus gravimetric procedures). Also, it makes a difference whether lipids are determined on a sub-sample of the test population, or for an aliquot from each fish. Hence, it can be important to know which lipid determination method was used.

1 *Growth dilution* refers to the decline in internal test substance concentration that can  
2 occur due to the growth of an organism (which may lead to an underestimation of the  
3 BCF that would result from a situation in which the fish are not growing). It is especially  
4 important for small (juvenile) fish (e.g. rainbow trout, bluegill sunfish and carp) that  
5 have the capacity for growth during the duration of a test with substances that have a  
6 slow elimination kinetics (e.g. Hendriks *et al.*, 2001). Growth dilution can be taken into  
7 account by measuring growth rate during the elimination phase (e.g. by monitoring the  
8 weight of the test organisms over time). An exponential growth rate constant ( $k_g$ ) can  
9 usually be derived from a plot of natural log(weight) against time. A growth-corrected  
10 elimination rate constant can then be calculated by subtracting the growth rate constant  
11 from the overall elimination rate constant ( $k_2$ ). Hence:

12 
$$\text{growth-corrected BCF} = k_1 / (k_2 - k_g)$$

13 where  $k_1$  is the uptake clearance [rate constant] from water (L/kg/day)

14  $k_2$  is the elimination rate constant ( $\text{day}^{-1}$ )

15  $k_g$  is the growth rate constant ( $\text{day}^{-1}$ )

16 Clearly, the influence of growth correction will be significant if  $k_g$  is a similar order of  
17 magnitude to  $k_2$ .

18 For older fish bioaccumulation studies, information on growth may not be available. In  
19 this case, an assessment of the likely significance of growth on the results should be  
20 made to determine what weight should be given to the study in the weight of evidence  
21 assessment. As noted in the OECD 305 TG (paragraph 32) juvenile fish may be fast  
22 growing at the life-stage (and size) they are tested in the OECD TG 305. Small Rainbow  
23 Trout (*Oncorhynchus mykiss*) are an example of this. In contrast, fish such as Zebra fish  
24 (*Danio rerio*) are usually adults and therefore significantly slower growing (for example  
25 see an analysis in Brooke & Crookes, 2012). In the absence of growth data, the  
26 uncertainty in a BCF value derived from a fast-growing fish will be greater than that for a  
27 slow growing fish, which is important for results near a regulatory threshold. Overall,  
28 any approach to using fish bioaccumulation data where growth data are not available  
29 needs to be considered on a case-by-case basis with justification for the conclusion  
30 drawn.

31

### 32 Fish dietary studies

33 Dietary studies require careful evaluation and in particular the following points should be  
34 considered in assessing the data from such a study:

- 35
- Was a positive control used and were the data acceptable?
  - Were the guts of the fish excised before analysis? The guts can sometimes contain undigested food and thus test chemical, which, for poorly assimilated or highly metabolised chemicals, will lead to erroneous (though precautionary) values being generated.
- 36  
37  
38  
39

- 1           • Is there any evidence to suggest the food was not palatable due to use of  
2           extremely high chemical concentrations in the food? This may be assessed by  
3           examining the growth of the fish during the course of the study.
- 4           • Was there homogeneity of the test substance in the spiked food? Further  
5           criteria for this are given in paragraph 113 of OECD TG 305.

6           The dietary study yields a number of important data that improve the potential for  
7           assessing biomagnification potential, including the dietary chemical absorption efficiency  
8           and the whole body elimination rate constant ( $k_2$ ) and half-life for substances for which  
9           this is impossible via the aqueous exposure route.

10          Annex 8 of the OECD TG 305 summarises some approaches currently available to  
11          estimate tentative BCFs from data collected in the dietary exposure study. This  
12          calculation is based on a model predicted uptake rate constant ( $k_1$ ) and the depuration  
13          rate constant ( $k_2$ ) determined from the dietary bioaccumulation study. For the PBT  
14          assessment, it is possible to translate the dietary experimental data to tentative BCFs for  
15          comparison against the BCF criteria outlined in Annex XIII. However, it should be noted  
16          that these calculated BCFs may be more uncertain than experimental BCFs due to the  
17          uncertainty in the  $k_1$  prediction. In particular,  $k_1$  is a function of chemical properties  
18          relating to the chemical transfer efficiency from water (e.g., membrane permeation or  
19          absorption efficiency), the physiology of the fish (body size, respiration rate) and the  
20          experimental conditions (e.g., dissolved oxygen concentrations, water temperature, gill  
21          water pH for ionic chemicals). Thus assuming  $k_1$  is accurately and appropriately  
22          predicted for the substance and the conditions of the experiment, the tentative BCF  
23          values could be determined. However, they should be considered as part of the body of  
24          evidence, and not used as the only values from which to draw conclusions in the PBT  
25          assessment.

26

27          For poorly soluble non-polar organic substances first order uptake and depuration  
28          kinetics is assumed, and more complex kinetic models should be used only for  
29          substances that do not follow first order kinetics. Several models are available to  
30          estimate a  $k_1$  value needed to calculate an aqueous BCF from a dietary bioaccumulation  
31          study. Although there is some variation in the results of the  $k_1$  models and the models  
32          are restricted to predominantly neutral organic substances, the 13 presented models  
33          span a range of a factor 2.7 for some examples of a hydrophobic potential PBT  
34          substances (Crookes and Brooke, 2011). The uncertainty of the  $k_1$  models and their  
35          applicability domains (e.g. mostly restricted to neutral organic chemicals but including  
36          some weakly acidic or basic substances as well, log  $K_{ow}$  above 3.5 etc.) require  
37          consideration for the factors mentioned above. The model of Sijm (1995) is mentioned in  
38          OECD 305 TG and may provide a reasonable first choice at this point in time. This model  
39          uses the fish weight ( $W$  in g) to estimate the  $k_1$  with the following allometric  
40          relationship:  $k_1 = 520 \cdot W^{-0.32}$ . Accordingly, no one model can be recommended over the  
41          others and results must be used with caution, with reference to assumed applicability  
42          domains. If the method of deriving a BCF from a dietary BMF study is used, estimates of  
43           $k_1$  should be derived according to all the models available to give a range of BCFs.

44          Besides the calculation of a BCF from the depuration phase, the laboratory BMF derived  
45          from the test can be compared with laboratory BMF values for substances with known

1 bioaccumulation potential in a benchmarking exercise. For example, such an approach  
2 has been described for dietary bioaccumulation studies with carp (Inoue, Hashizume et  
3 al. 2012). Based on a regression between BCF and BMF for nine compounds tested in  
4 this set-up, it was shown that a BCF value of 5000 L/kg, normalized to a lipid content of  
5 5%, corresponds to a lipid normalized BMF from the dietary test of 0.31 kg food/kg fish,  
6 and a BCF of 2000 L/kg corresponds to a BMF of 0.10 kg food/kg fish. Of the five  
7 substances that had a BCF value higher than 5000 L/kg, two of them had a BMF value in  
8 excess of 1. A different benchmarking could be obtained from aqueous and dietary  
9 bioaccumulation studies for perfluorinated compounds with rainbow trout (Martin et al.,  
10 2003a, b). A BCF value of 5000 L/kg corresponded to a BMF from the dietary test of  
11 0.49 kg food/kg fish, and a BCF of 2000 L/kg corresponded to a BMF of 0.36 kg food/kg  
12 fish. Of the three substances with a BCF > 2000, one had a BMF of 1.0, while the two  
13 others had substantially lower BMF values. These two different examples showed that  
14 there is no uniform relationship between BCF and BMF. Moreover, the studies emphasise  
15 the fact that even if a BMF from an OECD 305 dietary bioaccumulation test is found to be  
16 <1, it cannot be considered as a good discriminator for concluding substances not to be  
17 (very) bioaccumulative according to the BCF criteria of Annex XIII. Further examination  
18 of differences between BCF data (and criteria) and BMF data (and criteria) with mass  
19 balance models and with larger datasets may in future provide further insights into  
20 relationships between the two bioaccumulation metrics and their respective  
21 bioaccumulation criteria. If benchmarking is used for comparing dietary BMF values with  
22 BMF values for substances with a known bioaccumulation potential, it must be ensured  
23 that these BMF values were obtained under (or normalised to) similar conditions.

24 Additional information on the interpretation of the results can be found in an OECD  
25 guidance document that will accompany the OECD TG 305 fish bioaccumulation test  
26 guideline.

27 In conclusion, OECD TG 305 III: Dietary Exposure Bioaccumulation Fish Test provides a  
28 range of valuable information which should all be discussed in the bioaccumulation  
29 assessment. Paragraph 167 of the test guideline lists all the relevant measured and  
30 calculated data from the study which should be reported and considered for the  
31 bioaccumulation assessment, including the BMF values, substance assimilation efficiency  
32 and overall depuration rate constant. When interpreting the study results, the tentative  
33 calculated BCFs and a benchmarking exercise to compare the k<sub>2</sub> and BMF derived from  
34 the test with other substances with known bioaccumulation potential also provide useful  
35 evidence for the bioaccumulation assessment and are recommended to be reported. The  
36 k<sub>2</sub> (or half-life) value itself may be useful for the assessment of the bioaccumulation  
37 potential (see Chapter R.11 of the [Guidance on IR&CSA](#)).

38

### 39 Invertebrate tests

40 Data obtained using standard methods are preferred. Similar principles apply as for the  
41 evaluation of fish bioaccumulation data (e.g. the test concentration should not cause  
42 significant effects; steady-state conditions should be used, the aqueous concentration in  
43 the exposure vessels should be maintained, and should be below the water solubility of  
44 the substance; if radioanalysis is used it should be supported by parent compound  
45 analysis so that the contribution of metabolites can be assessed, etc.). Additional factors  
46 to consider include:

- 1           • In general, no data will be available to allow the BCF to be lipid normalised  
2           and so the BCF will normally be expressed on a whole body wet weight basis.  
3           However, for any new laboratory invertebrate bioaccumulation test, a  
4           measurement of lipid should be made.
- 5           • For tests with marine species, the solubility of the test substance may be  
6           significantly different in salt water than in pure water, especially if it is ionised  
7           (for neutral organic chemicals the difference is only a factor of about 1.3).
- 8           • Bivalves stop feeding in the presence of toxins (e.g. mussels may remain  
9           closed for up to three weeks before they resume feeding (Claudi & Mackie,  
10          1993)). Therefore, the acute toxicity of the substance should be known, and  
11          the test report should indicate whether closure has occurred.
- 12          • Since most test species tend to feed on particulates (including micro-  
13          organisms) or whole sediment, the assessment of exposure concentrations  
14          may need careful consideration if the test system is not in equilibrium,  
15          especially for hydrophobic substances. Tissue concentrations may also be  
16          overestimated if the gut is not allowed to clear.
- 17          • Whole sediment tests with benthic organisms tend to provide a B(S)AF, which  
18          can be a misleading indicator of bioaccumulation potential since it reflects  
19          sorption behaviour as well. A better indicator would be the BCF based on the  
20          freely dissolved (bioavailable) sediment pore water concentration. Ideally, this  
21          should be done using direct analytical measurement (which may involve  
22          sampling devices such as SPME fibres). If no analytical data are available, the  
23          pore water concentration may be estimated using suitable partition  
24          coefficients, although it should be noted that this might introduce additional  
25          uncertainty to the result.
- 26          • Many studies have shown that black carbon can substantially affect the  
27          strength of particle sorption and hence the bioavailability of a substance  
28          (Cornelissen *et al.*, 2005). Observed black carbon partition coefficients exceed  
29          organic carbon partition coefficients by up to two orders of magnitude. When  
30          interpreting data where the exposure system includes natural sediments it is  
31          therefore important to account for the possible influence of black carbon  
32          partitioning to avoid underestimation of the substance's bioaccumulation  
33          potential from the freely dissolved phase.
- 34          • Data on apparent accumulation in small organisms, such as unicellular algae,  
35          *Daphnia* and micro-organisms, can be confounded by adsorption to cell or  
36          body surfaces leading to higher estimates of bioconcentration than is in fact  
37          the case (e.g. cationic substances may adsorb to negatively charged algal  
38          cells). Adsorption may also result in apparent deviation from first order  
39          kinetics and may be significant for small organisms because of their  
40          considerably larger surface/volume ratio compared with that for larger  
41          organisms.

42          The validity of bioaccumulation data obtained from sediment organism toxicity tests  
43          must be considered on a case-by-case basis, because the duration of the test might not

1 be sufficient to achieve a steady-state (especially for hydrophobic substances). Also, any  
2 observed toxicity (e.g. mortality) may limit the usefulness of the results.

3

#### 4 **R.7.10.4.2 Non-testing data on aquatic bioaccumulation**

##### 5 **(Q)SAR models**

6 **DISCLAIMER: this section does not include the latest information on the use of (Q)SAR**  
7 **models as it has not been subject of updates since first publication.**

8 The evaluation of the appropriateness of QSAR results should be based on an overall  
9 evaluation of different QSAR methods and models. The assessment of the adequacy of a  
10 single QSAR requires two main steps, as described below. These concepts are also  
11 considered generically in Section R.6.1.

##### 12 Evaluation of model validity

13 A number of studies have evaluated the validity of various BCF (Q)SAR models.  
14 Important parameters are the correlation coefficient ( $R^2$  value), standard deviation ( $SD$ )  
15 and mean error ( $ME$ ).  $SD$  and  $ME$  are better descriptors of method accuracy than the  $R^2$   
16 value.

17 Among the QSAR models based on the correlation between BCF and  $K_{ow}$ , Meylan *et al.*  
18 (1999) compared their proposed fragment-based approach with a linear (Veith & Kosian,  
19 1983) and bilinear (Bintein *et al.*, 1993) model, using a data set of 610 non-ionic  
20 compounds. The fragment method provided a considerably better fit to the data set of  
21 recommended BCF values than the other two methods, as shown by the higher  $R^2$  value,  
22 but more importantly, a much lower  $SD$  and  $ME$ .

23 Some studies have also compared the performance of models based on molecular  
24 connectivity indices,  $K_{ow}$  and fragments (e.g. Lu *et al.*, 2000, Hu. *et al.*, 2005).  
25 Gramatica and Papa (2003) compared their BCF model based on theoretical molecular  
26 descriptors selected by Genetic Algorithm with the molecular connectivity index approach  
27 and the BCFWIN model. The use of apparently more complex descriptors was  
28 demonstrated to be a valuable alternative to the traditional log  $K_{ow}$  approach.

##### 29 Assessment of the reliability of the individual model prediction

30 Evaluation of the reliability of a model prediction for a single chemical is a crucial step in  
31 the analysis of the adequacy of a QSAR result. Several methods are currently available  
32 but none of these provide a measure of overall reliability. It is important to avoid the  
33 pitfall of simply assuming that a model is appropriate for a substance just because the  
34 descriptor(s) fall with the applicability domain. Several aspects should be considered and  
35 the overall conclusion should be documented (e.g. Dimitrov *et al.*, 2005b):

- 36 • Preliminary analysis of physico-chemical properties that may affect the quality  
37 of the measured endpoint significantly, such as molecular weight, water  
38 solubility, volatility, and ionic dissociation.
- 39 • Molecular structural domain (e.g. are each of the fragments and structural  
40 groups of the chemical well enough represented in the QSAR training set?).

- 1           • Mechanistic domain (e.g. does the chemical fit in the mechanistic domain of  
2           the model?).
- 3           • Metabolic domain (relating to information on likely metabolic pathways within  
4           the training set, identification of metabolites that might need to be analysed  
5           in addition to the parent compound).

6 Some of the steps for defining the model domain can be skipped depending on the  
7 availability and quality of the experimental data used to derive the model, its specificity  
8 and its ultimate application.

9 It should also be noted that BCF models tend to have large uncertainty ranges, and the  
10 potential range of a predicted value should be reported. Predictions for substances with  
11  $\log K_{ow} > 6$  need careful consideration, especially if they deviate significantly from  
12 linearity (see Section [R.7.10.5](#)).

13 **Error! Reference source not found.** lists some commonly used models that can be  
14 used to help make decisions for testing or regulatory purposes if a chemical category-  
15 specific QSAR is not available. The registrant may also choose other models if they are  
16 believed to be more appropriate. The table indicates some of the important  
17 considerations that need to be taken into account when comparing predictions between  
18 the models.

19

20

21 **Table R.7.10–2 Commonly used QSAR models for predicting fish BCFs**

22 **DISCLAIMER: this table does not include the latest information on the use of (Q)SAR**  
23 **models as it has not been subject of updates since first publication.**

| Model                      | Training set log $K_{ow}$ | Chemical domain   | Comments   | Reference                            |
|----------------------------|---------------------------|---|--|--------------------------------------|
| Veith <i>et al.</i> , 1979 | 1 to 5.5                  | Based on neutral, non-ionized chemicals (total of 55 chemicals).                    | Not applicable to ionic or partly ionized substances, and organometallics.   | Veith <i>et al.</i> , 1979; EC, 2003 |
| Modified Connell           | 6 to ~9.8                 | Based mainly on non-metabolisable chlorinated hydrocarbons (total of 43 chemicals). | Claimed log $K_{ow}$ range should be taken with caution: the model accounts for non-linearity above log $K_{ow}$ 6, but is unreliable at log $K_{ow} > 8$ .<br><br>Used historically for substances with a log $K_{ow} > 6$ , but other models are now more appropriate (see below). | EC, 2003                             |

|                     |         |  |   |                                |
|---------------------|---------|--|---|--------------------------------|
| EPIWIN <sup>®</sup> | 1 to ~8 | Wide range of classes included; 694 chemicals in data set used.  | Carefully check any automatic assignment of chemical class. Assess if sub-structures of substance are adequately represented in the training set.<br><br>May be unreliable above log K <sub>ow</sub> of ~6. | Meylan <i>et al.</i> , 1999    |
| BCF <sub>max</sub>  | 1 to ~8 | Wide range of classes covered; includes BCF data from dietary tests on hydrocarbons (log K <sub>ow</sub> <7 only). | Preferred model for highly hydrophobic (log K <sub>ow</sub> > 6) substances (due to conservatism). Can account for factors that can reduce BCF (e.g. metabolism, ionization and molecular size).            | Dimitrov <i>et al.</i> , 2005a |

2 ECHA's [Practical Guide 5: How to use and report \(Q\)SARs](#) provides guidance on how to  
3 use and report (Q)SAR predictions under REACH. The Practical Guide also includes a list  
4 of QSAR models suitable for predicting bioaccumulation in aquatic species ([Table](#)  
5 [R.7.10–1](#)).

6

## 7 **Read-across and categories**

8 When applying read-across based on BCF two important aspects have to be considered,  
9 i.e. the lipophilicity and the centre of metabolic action for both the source and target  
10 substances.

11 The BCF value of a substance is generally positively correlated with its hydrophobicity.  
12 Therefore, if the substance to be evaluated has a higher log K<sub>ow</sub> than an analogue  
13 substance for which a BCF is available, the BCF value has to be corrected. The use of the  
14 same factor of difference as for K<sub>ow</sub> will be a reasonable worst-case estimate, because  
15 generally the relationship between BCF and K<sub>ow</sub> is slightly less than unity. For example, if  
16 the substance to be evaluated has one methyl group more than the compound for which  
17 a BCF value is available, the log K<sub>ow</sub> will be 0.5 higher and the estimated BCF from read-  
18 across is derived from the known BCF multiplied by a factor of 10<sup>0.5</sup>. In principle, this  
19 correction should give reasonable estimates as long as the difference in log K<sub>ow</sub> is  
20 limited. However, the addition of one ethyl group already leads to a difference in log K<sub>ow</sub>  
21 of more than one log unit or a factor of 10 on the BCF value. If the substance to be  
22 evaluated has a *lower* log K<sub>ow</sub> than the substance for which a BCF value is available, care  
23 must be taken not to adjust the value too far downwards.

24 If the substance has such a large molecular size (see Section [R.7.10.3.4](#)) that the uptake  
25 of the substance by an organism might be hindered, a different approach should be  
26 followed. The addition of an extra substituent that leads to an increase of the log K<sub>ow</sub>  
27 value does not necessarily lead to a higher BCF value in this case. On the contrary, such  
28 an addition may cause the substance to be less easily taken up by the organism, which  
29 may result in a lower instead of a higher BCF value. In such cases the ideal compound  
30 for read-across is a structurally similar compound with a slightly smaller molecular size.

1 Another important aspect is the capability of fish to metabolise substances to more polar  
2 compounds, leading to a lower BCF value (in some circumstances metabolism could lead  
3 to the formation of more bioaccumulative substances). Small changes to molecular  
4 structure can be significant. For example, metabolism may be inhibited if a substituent is  
5 placed on the centre of metabolic action. If read-across is applied, it must be recognised  
6 that the presence of such a substituent on the substance to be evaluated may lead to a  
7 strongly reduced metabolism in comparison with the substance for which the BCF is  
8 known. As a consequence, the BCF value may be underestimated. If there are  
9 indications of metabolism for the analogue substance for which a BCF value is available,  
10 it must be examined if the same potential for metabolism is present in the substance  
11 and the species to be evaluated.

12 An indication of metabolism can be obtained by comparing measured BCF values with  
13 predicted values from QSARs based on  $\log K_{ow}$ . These QSARs are based on neutral  
14 organic compounds that are not metabolised strongly. If it appears that the BCF of a  
15 substance lies significantly below the estimate from the QSAR (e.g. more than one log  
16 unit), this is a strong indication for metabolism of the compound. Further indications of  
17 metabolism may be provided by *in vitro* methods (see Section [R.7.10.3.1](#)) and  
18 inferences from mammals (see Section [R.7.10.3.4](#)).

19

#### 20 **R.7.10.4.3 Field data on aquatic bioaccumulation**

21 Bioaccumulation data obtained from field studies can differ from those measured in  
22 laboratory tests with fish or aquatic invertebrates. This is because the latter are designed  
23 to provide data under steady-state conditions, and generally involve water-only  
24 exposures, little or no growth of the test species, a consistent lipid content in the  
25 organism and its food, constant chemical concentrations, and constant temperature.  
26 These conditions are not achievable in field settings, where there are also additional  
27 influences such as differences in food diversity and availability, competition, migration,  
28 etc. Nevertheless, field biomonitoring data are the ultimate indicator of whether a  
29 substance's bioaccumulation potential is expressed in nature. This is discussed further in  
30 Section R.11.4.1.2 in Chapter R.11 of the [Guidance on IR&CSA](#).

31 Caution should be used when interpreting bioaccumulation factors measured in studies  
32 with mesocosms or caged animals, because key environmental processes that occur in  
33 larger systems might not have been known or reported. For example, it should be  
34 confirmed whether exposure concentrations in a mesocosm were stable throughout the  
35 observation or if bioaccumulation may have taken place before the start of the  
36 observation period. Furthermore, sediment-water disequilibrium can be influenced by  
37 water column depth and primary production, which will influence chemical bioavailability  
38 and uptake in the organisms sampled. Similarly, caged animals may not have the same  
39 interactions in the environment as wild animals, leading to differential uptake of the test  
40 chemical in food or water. It is also imperative for caged animal studies that sufficient  
41 duration be allowed so that the organisms can approach a steady state (e.g. Burkhard *et al.*,  
42 2003 & 2005).

43 The precision or uncertainty of a field B(S)AF determination is defined largely by the  
44 total number of samples collected and analysed. For practical reasons, precision of the  
45 measurements may be balanced against the costs associated with sample collection and

1 analysis, and in many cases, pooling of samples is required to limit costs associated with  
2 the analytical analyses. Gathering and reporting too little information is far worse than  
3 providing too much information. The adequacy of the data on the intended purpose  
4 depends on their quality, and data from a field study that will be used to quantify  
5 bioaccumulation should ideally report the following:

- 6 • sampling design (site selection, spatial resolution, frequency of determination,  
7 etc.) and details of the sampling methodology, sample handling, sample  
8 storage and delivery conditions and stability, steps taken to reduce  
9 contamination, and of all equipment being used;
- 10 • description of analytical methods (including use of field blanks, procedural and  
11 instrumental blanks in analysis, laboratory pre-treatment, standard reference  
12 materials, etc.), as well as evidence of quality control procedures;
- 13 • spatial and temporal gradients in substance concentrations – in particular,  
14 care should be taken that the samples used to derive bioaccumulation factors  
15 are collected at the same time from the same location, and sufficient details  
16 provided to relocate the sampled site. Samples grabbed randomly without  
17 consideration of the organism's home range will, in high likelihood, have poor  
18 predictive ability for substance residues in the organisms because the water  
19 (and/or sediment) data will not be representative of the organism's actual  
20 exposure (Burkhard, 2003);
- 21 • physical details of the site, including temperature, salinity, direction and  
22 velocity of water flow, water/sediment depth and physico-chemical properties  
23 (e.g. particulate organic carbon and dissolved organic carbon levels);
- 24 • details of the organisms being analysed, including species, sex, size, weight,  
25 lipid content and life history pattern (e.g. migration, diet, and food web  
26 structure (which may be determined using measurements on nitrogen or  
27 carbon isotopes (Kiriluk *et al.*, 1995)) and composition). For resident species,  
28 the sample collection should be fairly straightforward. Migratory species may  
29 present special challenges in determining which food, sediment, or water  
30 sample should be used to calculate the BAF;
- 31 • information enabling an assessment of the magnitude of sorption coefficients  
32 to particulate matter, e.g. whether sorption is controlled by organic carbon or  
33 black carbon;
- 34 • details of data handling, statistical analysis and presentation; and
- 35 • any other detailed information that is important for understanding or  
36 interpreting the field data.

37 The Arctic Monitoring and Assessment Programme (AMAP, 2001) has published  
38 recommendations with regard to assessing the quality of monitoring data, suggesting  
39 that only data from studies with documented quality assurance for all or some stages of  
40 the data gathering process should be used for determining spatial and temporal trends  
41 and other types of data interpretations. If no information is available on quality  
42 assurance procedures, but the results are consistent with other reports concerning the  
43 same sample types, the data can be used to show relative trends (assuming that they

1 are internally consistent). If there is no evidence of quality assurance or if the data are  
2 incompatible with other studies, the results should not be used. In addition, expert  
3 judgement will usually be required on a case-by-case basis.

4 Burkhard (2003) performed a series of modelling simulations to evaluate the underlying  
5 factors and principles that drive the uncertainty in measured B(S)AFs for fish, and to  
6 determine which sampling designs minimize those uncertainties. Temporal variability of  
7 substance concentrations in the water column, and the metabolism rate and  $K_{ow}$  for the  
8 substance appear to be dominant factors in the field-sampling design. The importance of  
9 temporal variability of concentrations of substances in water increases with increasing  
10 rate of metabolism. This is due to the fact that the rate of substance uptake from water  
11 (which is independent of the rate of substance metabolism) becomes more important in  
12 controlling the total substance residue in the fish with increasing rate of metabolism.  
13 Spatial variability of the substance concentrations, food web structure, and the  
14 sediment-water column concentration quotient had a lesser importance upon the overall  
15 design. The simulations also demonstrated that collection of composite water samples in  
16 comparison to grab water samples resulted in reductions in the uncertainties associated  
17 with measured BAFs for higher  $K_{ow}$  substances, whereas for lower  $K_{ow}$  substances the  
18 uncertainty in the BAF measurement increases.

19 Data on biomagnification (TMF, BMF or B-values) should be calculated based on lipid-  
20 normalised concentrations (unless lipid is not important in the partitioning process, e.g.  
21 for many inorganic compounds).

22 Chemical concentrations from migratory populations of fish, marine mammals and birds  
23 may be available. Because sampling of satellite- or radio-tagged populations is  
24 extremely rare, noting the known migration routes and when sampling occurred along  
25 those historical timelines can be important for identifying trends in contaminant  
26 exposure and cycles of bioaccumulation and release of contaminants from fat stores  
27 (Weisbrod *et al.*, 2000 & 2001). If the migratory history of the sampled population is  
28 unknown, as is frequently the case for fish and invertebrates, stating what is known  
29 about the animals' expected duration at the site of collection can be insightful when  
30 comparing BAF values from multiple populations or sites.

#### 31 **R.7.10.4.4 Other indications of bioaccumulation potential**

32 High-quality experimentally derived  $K_{ow}$  values are preferred for organic substances.  
33 When no such data are available or there is reasonable doubt about the accuracy of the  
34 measured data (e.g. due to problems with analytical methods or surfactant properties),  
35 the log  $K_{ow}$  value should be calculated using validated QSARs. If this is not possible (e.g.  
36 because the substance does not fall within the model domain), an estimate based on  
37 individual *n*-octanol and water solubilities may be possible. If multiple log  $K_{ow}$  data are  
38 available for the same substance, the reasons for any differences should be assessed  
39 before selecting a value. Generally, the highest valid value should take precedence.  
40 Further details are provided in Section R.7.1 in Chapter R.7a of the [Guidance on IR&CSA](#).

41 Further guidance on the evaluation of mammalian toxicokinetic data is provided in  
42 Sections [0](#) and [R.7.12](#).

43

#### 1 **R.7.10.4.5 Exposure considerations for aquatic bioaccumulation**

2 Column 2 of Annex IX to REACH states that a study is not necessary if direct and indirect  
3 exposure of the aquatic compartment is unlikely (implying a low probability of – rather  
4 than low extent of – exposure). Opportunities for exposure-based waiving will therefore  
5 be limited. Furthermore, it should be noted, that if the registrant cannot derive a  
6 definitive conclusion (i) (“The substance does not fulfil the PBT and vPvB criteria”) or (ii)  
7 (“The substance fulfils the PBT or vPvB criteria”) in the PBT/vPvB assessment using the  
8 relevant available information, the only possibility to refrain from testing (or generating  
9 other necessary information) is to treat the substance “*as if it is a PBT or vPvB*” (see  
10 Chapter R.11 for details). Since bioaccumulation is such a fundamental part of the  
11 assessment of the hazard and fate of a substance, it may be omitted from further  
12 consideration on exposure grounds only under exceptional circumstances. This might  
13 include, for example, cases where it can be reliably demonstrated (by measurement or  
14 other evidence) that there is no release to the environment at any stage in the life cycle.  
15 An example might be a site-limited chemical intermediate that is handled under rigorous  
16 containment, with incineration of any process waste. The product does not contain the  
17 substance as an impurity, and is not converted back to the substance in the  
18 environment. Potential losses only occur from the clean-down of the process equipment,  
19 and the frequency and efficiency of cleaning (and disposal of the waste) should be  
20 considered.

21 It should be noted that if bioaccumulation data are only needed to refine the risk  
22 assessment (i.e. they will not affect the classification or PBT assessment), other  
23 exposure factors should be considered before deciding on the need to collect further data  
24 from a vertebrate test. For example, further information on releases or environmental  
25 fate (such as persistence) may be useful.

#### 26 **R.7.10.4.6 Remaining uncertainty for aquatic bioaccumulation**

27 Both the BCF and BMF should ideally be based on measured data. In situations where  
28 multiple BCF data are available for the same substance, organism, life stage, test  
29 duration and condition, the possibility of conflicting results might arise (e.g. due to  
30 differing lipid contents, ratio of biomass/water volume, ratio of biomass/concentration of  
31 chemical, timing of sampling, feeding of test fish, etc.). In general, BCF data from the  
32 highest quality tests with appropriate documentation should be used in preference, and  
33 the highest valid value (following lipid normalisation, except for cases where lipid is not  
34 the main compartment of accumulation) should be used as the basis for the assessment.  
35 When more reliable BCF values are available for the same species and life stage etc., the  
36 geometric mean (of the lipid normalised values, where appropriate) may be used as the  
37 representative BCF value for that species for bioaccumulation-- and risk assessment. The  
38 GHS criteria guidance mention that this is applicable in relation to chronic aquatic hazard  
39 classification when four or more such data are available (OECD, 2001).

40 If measured BCF values are not available, the BCF can be predicted using QSAR  
41 relationships for many organic substances. However, consideration should be given to  
42 uncertainties in the input parameters. For example, due to experimental difficulties in  
43 determining both  $K_{ow}$  and BCF values for substances with a log  $K_{ow}$  above six, QSAR  
44 predictions for such substances will have a higher degree of uncertainty than less

1 hydrophobic substances. Any uncertainty in the derived BCF may be taken into account  
2 in a sensitivity analysis.

3 The availability of measured BMF data on predatory organisms is very limited at present.  
4 The default values given in [Table R.7.10–3](#) should be used as a screening approach  
5 designed to identify substances for which it may be necessary to obtain more detailed  
6 information on variables influencing the secondary poisoning assessment. These are  
7 based on data published by Rasmussen *et al.* (1990), Clark & Mackay (1991), Evans *et al.*  
8 *et al.* (1991) and Fisk *et al.* (1998), with the assumption of a relationship between the  
9 magnitude of the field-BMF, the BCF and the log  $K_{ow}$ . It is recognised that the available  
10 data are only indicative, and that other more complex intrinsic properties of a substance  
11 may be important as well as the species under consideration (e.g. its biology in relation  
12 to uptake, metabolism, etc.). It is recognised that, for the purpose of secondary  
13 poisoning assessment, the BMF to be used should be a value representing  
14 biomagnification in field conditions. A BMF resulting directly from a dietary fish  
15 bioaccumulation test (OECD TG 305) cannot be used without modifications as a BMF for  
16 secondary poisoning assessment.

17 When a BMF for secondary poisoning assessment cannot be derived on the basis of  
18 experimental or field data, a BMF may be estimated using log  $K_{ow}$  data as described in  
19 [Table R.7.10–3](#). The second column of this table shows (ranges of) BCF values. These  
20 values are meant to help select default BMF values if experimental BCF data are  
21 available. The programme BCFBAF within the EPISuite 4.11 could also be used to  
22 estimate BMF/TMF values for hydrophobic substances in the pelagic environment. This  
23 could be done by comparing the BAF values calculated at different trophic levels after  
24 lipid normalisation of the BAF (lipid contents are 10.7%, 6.85% and 5.98% in the model  
25 for the upper, middle and lower trophic levels, respectively).

26 **Table R.7.10–3 Default BMF values for organic substances for secondary**  
27 **poisoning assessment (not applicable for PBT/vPvB assessment)**

| log $K_{ow}$ of substance | Measured BCF (fish) | BMF |
|---------------------------|---------------------|-----|
| <4.5                      | < 2,000             | 1   |
| 4.5 - <5                  | 2,000-5,000         | 2   |
| 5 - 8                     | > 5,000             | 10  |
| >8 - 9                    | 2,000-5,000         | 3   |
| >9                        | < 2,000             | 1   |

28

29 The recommended BCF triggers are less conservative than the log  $K_{ow}$  triggers because  
30 they more realistically take the potential for metabolism in biota (i.e. fish) into account.  
31 Due to this increased relevance, the use of measured BCF values as a trigger would take  
32 precedence over a trigger based on log  $K_{ow}$ .

33 If no BCF or log  $K_{ow}$  data are available, the potential for bioconcentration in the aquatic  
34 environment may be assessed by expert judgement (e.g. based on a comparison of the

1 structure of the molecule with the structure of other substances for which  
2 bioconcentration data are available).

### 3 **R.7.10.5 Conclusions for aquatic bioaccumulation**

4 In view of the importance of this endpoint in the assessment of a chemical, a cautious  
5 approach is needed. All types of relevant data as described in the previous sections should  
6 be considered together in a weight-of-evidence approach in order to derive a conclusion.

7 If the different lines of evidence coherently point to the same direction, or it is possible  
8 to plausibly explain the discrepancies between different data types, it may be possible to  
9 draw a conclusion on the bioaccumulation potential for PBT/vPvB assessment and/or to  
10 derive a BCF and BMF for secondary poisoning assessment without generating new  
11 information.

12 Reliable measured fish BCF data on the substance itself, if such data are available, are  
13 normally considered the most representative information on the bioaccumulation  
14 potential. The fish BCF is widely used as a surrogate measure for bioaccumulation  
15 potential in a wide range of gill-breathing aquatic species (e.g. crustacea). It should be  
16 noted that:

- 17 - Experimental BCF data on highly lipophilic substances (e.g. with log  $K_{ow}$  above 6) will  
18 have a much higher level of uncertainty than BCF values determined for less  
19 lipophilic substances. In the absence of data on other uptake routes, it is assumed  
20 that direct uptake from water accounts for the entire intake for substances with a  
21 log  $K_{ow}$  below  $\sim 4.5$  (EC, 2003). For substances with a log  $K_{ow} \geq 4.5$ , other uptake  
22 routes such as intake of contaminated food or sediment may become increasingly  
23 important.
- 24 - The BCF still only gives a partial picture of accumulation (especially for very  
25 hydrophobic substances), and additional data on uptake and depuration kinetics,  
26 metabolism, organ specific accumulation and the level of bound residues are also  
27 useful. Such data will not be available for most substances (OECD, 2001).

28 Furthermore, OECD TG 305 III: Dietary Exposure Bioaccumulation Fish Test provides a  
29 range of valuable experimental information which can be considered for the  
30 bioaccumulation assessment. Paragraph 167 of the test guideline lists all the relevant  
31 measured and calculated data from the study which should be reported and considered  
32 for the bioaccumulation assessment, including the BMF values, substance assimilation  
33 efficiency and overall depuration rate constant. Further guidance on the OECD TG 305 is  
34 available (OECD, 2016). Reliable measured BCF/BAF data from aquatic invertebrates can  
35 be used, if available, as part of a weight of evidence assessment. As described in  
36 Sections [R.7.10.3/R.7.10.4](#) and section [R.7.10.6](#), existing information on field studies, *in*  
37 *vitro* fish metabolism studies and information on toxicokinetics should be considered as  
38 part of a weight-of-evidence approach as well. *In vitro* fish metabolism studies can  
39 provide useful evidence of the potential for metabolism and thus may indicate a low  
40 bioaccumulation potential.

41 Another line of evidence concerns predicted BCF/BAF/BMF values from validated QSAR  
42 models. Models that use measured data as input terms may be preferable to those that

1 require calculated theoretical descriptors. Data from analogue substances can also be  
2 considered where relevant.

3 A further line of evidence concerns indications and rules based on physico-chemical  
4 properties. The log  $K_{ow}$  is a useful screening tool for many substances, and it is generally  
5 assumed that non-ionised organic substances with a log  $K_{ow}$  below 3 (4, GHS) are not  
6 significantly bioaccumulative.

7 These lines of evidence can be assessed together as part of an overall *Weight of*  
8 *Evidence* to decide on the need for additional testing when a fully valid fish test is  
9 unavailable. In principal, the available information from testing and non-testing  
10 approaches, together with other indications such as physico-chemical properties, must  
11 be integrated to reach a conclusion that is fit for the regulatory purpose regarding the  
12 bioaccumulation of a substance. The following scheme presents the thought processes  
13 that must be considered for substances produced or imported at 100 t/y or above.

14 If conclusions on bioaccumulation potential cannot be drawn for the purpose of PBT/vPvB  
15 assessment (when relevant) and/or a BCF and a BMF cannot be derived for the purpose  
16 of secondary poisoning assessment based on available data, further data generation is  
17 necessary. The type of additional data to be generated depends on the available dataset  
18 and animal data should be generated as a last resort. If (new) animal data are needed, a  
19 flow-through bioaccumulation test according to OECD 305 TG is the preferred option.  
20 Where it is not technically feasible to perform an aquatic fish bioaccumulation study  
21 under flow-through conditions, next preference is to generate new data with a fish  
22 dietary study. Also, measurements of existing specimen bank samples may be used for  
23 measuring field bioaccumulation. However, such alternative to experimental *in vivo*  
24 testing may only serve data generation in specific, well justified cases due to many  
25 uncertainties regarding field data. The possibility of generating new high quality field  
26 data with new samples is not excluded, in case animal use cannot be avoided. However,  
27 such new animal studies should only be considered in specific cases where other types of  
28 experimental studies are expected not to provide additional information on  
29 bioaccumulation.

30 It should also be noted that substances with a combination of log  $K_{ow} > 2$  and log  $K_{oa} >$   
31 4.5 have the potential to accumulate more preferably into air-breathing organisms than  
32 aquatic organisms. Therefore, a justification should be provided if such accumulation  
33 path into air-breathing organisms is not relevant for the assessment or, if relevant, a  
34 case-by-case assessment of risks in air-breathing organisms should be carried out (see  
35 Sections [R.7.10.8](#) to [0](#)).

36 It should be noted, that currently no generic guidance on a systematic weight-of-  
37 evidence approach can be provided but basic principles are available for reference in a  
38 [Practical Guide](#) on *How to use alternatives to animal testing to fulfil your information*  
39 *requirements for REACH registration non-animal testing*.

40

41

42

43

## 1 **Step 1 – Characterisation of the substance**

### 2 Verification of the structure:

3 This information is essential for the potential use of non-testing techniques (e.g. (Q)SAR  
4 models). In the case of multi-constituent substances, it may be necessary to consider  
5 two or more structures, if a single representative structure is not considered sufficient  
6 (see [Appendix R.7.10-3](#)).

### 7 Physico-chemical properties of the substance:

8 Gather information on the physico-chemical properties relevant for assessment of  
9 bioaccumulation (see Section [R.7.10.3](#)), i.e. vapour pressure, water solubility and log  $K_{ow}$   
10 (and, if available, octanol solubility, molecular weight (including size and maximum  
11 diameter, if relevant), Henry's law constant, adsorption ( $K_{oc}/K_p$ ) and pKa).

### 12 Information about degradation of the substance:

13 Gather information on degradation (including chemical reactivity, if available) and  
14 degradation products formed in environment (see Section [R.7.10.3](#)). This may include  
15 possible metabolites formed due to metabolism in organisms (e.g. based on available  
16 toxicokinetic data in fish or mammalian species, if available). Based on this information,  
17 conclude whether degradation products/metabolites should be included in the evaluation  
18 of the parent substance or not.

### 19 Preliminary analysis of bioaccumulation potential:

20 Based on the above considerations, make a preliminary analysis of the bioaccumulation  
21 potential of the substance (and degradation products/metabolites, if relevant):

- 22 • Examine information on log  $K_{ow}$ . Does this suggest a potential for  
23 bioaccumulation at environmentally relevant pH (i.e.  $K_{ow} > 3$ )? If so, then:
  - 24 - If log  $K_{ow} < 6$ , estimate a preliminary BCF according to a linear model  
25 (e.g. Veith *et al.* (1979) and Meylan *et al.* (1999)).
  - 26 - If log  $K_{ow} > 6$ , the quantitative relationships between BCF and  $K_{ow}$  are  
27 uncertain. A preliminary BCF of 25,000 (corresponding to a log  $K_{ow}$  of  
28 6) should be assumed in the absence of better information (see  
29 below).
  - 30 - Guidance on ionisable substances is given in [Appendix R.7.10-3](#).
  - 31 - A series of molecular and physico-chemical properties can be used as  
32 indicators for a reduced uptake in relation to the PBT assessment (see  
33 Chapter R11 for further guidance). If it is concluded that the B criterion  
34 will not be met, a preliminary BCF of 2,000 may be assumed as a  
35 worst case (e.g. for the Chemical Safety Assessment).
  - 36 - Substance characterisation may highlight that the substance is  
37 'difficult' (e.g. it may have a high adsorptive capacity (e.g. log  $K_p > 3$ ),  
38 or it might not be possible to measure or predict a  $K_{ow}$  value); further  
39 guidance on some common problems is given in [Appendix R.7.10-3](#).

- 1                   - Identify relevant exposure routes: only via water or by water and oral  
2                   exposure (e.g. for substances with  $\log K_{ow} > 4.5$ ).

### 3 **Step 2 – Identification of possible analogues**

4 Search for experimental bioaccumulation data on chemical analogues, as part of a group  
5 approach if relevant (see Section [R.7.10.3.2](#)). Justify why the chosen analogues are  
6 considered similar (as regards bioconcentration potential). Supplementary questions to  
7 be asked at this stage include:

- 8                   • Does the substance belong to a group of substances that are known to have a  
9                   potential to accumulate in living organisms (e.g. organotin compounds, highly  
10                  chlorinated organic substances, etc.)?
- 11                  • Is  $\log K_{ow}$  a relevant predictor for bioaccumulation (i.e. based on expected  
12                  accumulation in lipid)? Experimental evidence or other indications of sorption  
13                  mechanisms other than partitioning into lipids (e.g. metals, perfluorinated  
14                  compounds) should be thoroughly evaluated. In case there are reasons to  
15                  believe that the substance may bioaccumulate but not in fat, a BCF study  
16                  should be performed since there are currently no non-testing methods  
17                  available to estimate bioaccumulation potential quantitatively for such  
18                  compounds.

### 19 **Step 3a – Evaluation of existing *in vivo* data**

20 Available *in vivo* data may include invertebrate (including algal) BCFs, fish BCFs, BMFs  
21 for fish from dietary studies (which can be converted to a BCF), BSAFs for invertebrates,  
22 BMFs for predators from field studies, and toxicokinetic data from mammals (and birds if  
23 available). Assess all available results (including guideline and non-guideline tests) for  
24 their reliability according to the criteria provided in Section [R.7.10.4.1](#). If data from one  
25 or several standard tests are available continue with the evaluation of this type of data in  
26 step 4b (below).

27 Other indications of the substance's biomagnification potential in the field should also be  
28 considered. For example, results from field studies (including monitoring data) may be  
29 used to support the assessment of risks due to secondary poisoning and PBT  
30 assessment. Reliable field data indicating biomagnification may indicate that the BCF of  
31 the substance is approximately equal to or greater than the BCF estimated from the  $K_{ow}$ .

### 32 **Step 3b – Evaluation of non-testing data**

33 (Q)SARs based on  $K_{ow}$  are generally recommended if  $K_{ow}$  is a good predictor of  
34 bioconcentration. Use of (Q)SARs based on water solubility or molecular descriptors may  
35 also be considered, although these may be associated with higher uncertainty. The  
36 selection of a particular QSAR should always be justified. If several generally reliable  
37 QSAR predictions are available, the reason for the difference should be considered.  
38 Expert judgement should be used, following the approach outlined in Section R.6.1. In  
39 general, a cautious conclusion should be drawn, using the upper range of the predicted  
40 BCF values of the most relevant and reliable QSAR model(s).

41 If analogues with experimental BCF data are available, an indication of the predictability  
42 of the selected (Q)SAR(s) for the substance can be achieved by comparing the predicted

1 and experimental results for the analogues. Good correlation for the analogues increases  
2 the confidence in the BCF prediction for the substance (the reverse is true when the  
3 correlation is not good). When read-across is done it is always necessary to explain and  
4 justify why the analogue is assumed to be relevant for the substance under assessment  
5 (including how closely related the analogue is in relation to the bioaccumulation  
6 endpoint).

7 See Section [R.7.10.4](#) and the chapter for grouping of substances (Section R.6.2) for  
8 further guidance.

### 9 **Step 3c – Evaluation of *in vitro* data**

10 If reliable *in vitro* metabolism data are available, then they may be used as supporting  
11 information to produce an estimated BCF or a qualitative indication for a reduced BCF  
12 due to metabolism. Further information is available in Section [R.7.10.3.1](#).

### 13 **Step 4a – Weight-of-Evidence assessment**

14 Section 4.1 of the ECHA Practical guide on “How to use alternatives to animal testing to  
15 fulfil your information requirements for REACH registration” (ECHA (2016)) provides a  
16 general scheme for building a Weight-of-Evidence approach. It should be noted that  
17 further development of the Weight-of-Evidence approach is on-going and further ECHA  
18 methodology on this may become available in the near future. It is therefore not possible  
19 to give any specific recommendations on weight-of-evidence approaches at this stage.

20 A tiered assessment strategy for fish bioaccumulation assessment has recently been  
21 proposed, but this strategy has not yet been tested in a regulatory context (Lillicrap,  
22 Springer and Tyler, 2016). Further discussion of how to use the weight of evidence  
23 approach in PBT assessment is available in ECHA guidance Chapter R.11: PBT/vPvB  
24 assessment.

25

### 26 **Step 4b – Weight of Evidence for multiple experimental BCF data**

27 Studies that do not match evaluation criteria in Section [R.7.10.4.1](#) should be considered  
28 of lower reliability and should normally be assigned a lower weight.

29 If several reliable fish data exist, reasons for any differences should be sought (e.g.  
30 different species, sizes, etc. – see Section [R.7.10.4.1](#)). Data should be lipid-normalised  
31 and corrected for growth dilution where possible (and appropriate) to reduce inter-  
32 method variability. Particular scrutiny should be given if results from the tests are close  
33 to the B or vB thresholds. If differences still remain (e.g. high quality BCF values for  
34 different fish species are available), the highest reliable lipid-normalised BCF value  
35 should normally be selected. Alternatively, the approach indicated by Section 4.1.3.2.4.3  
36 of the Guidance on the application of the CLP criteria could be considered. This suggests  
37 using a geometric mean where four or more equivalent ecotoxicity tests are available.  
38 Overall, the approach used should be justified, and be supported by the weight of  
39 evidence available.

40 Organ-specific BCF data may be used on a case-by-case basis if adequate  
41 pharmacokinetic information is available (see Section [R.7.10.4.1](#)).

1 In general, the aim is to use data from experimental studies and other indicators to  
2 obtain a quantitative estimate of a fish BCF. However, reliable BCF data on molluscs may  
3 also be used directly. It should be noted that invertebrate BCFs are not equivalent to fish  
4 BCFs, since the physiological processes that govern bioconcentration in invertebrates  
5 differ substantially from those in fish. In particular, body compartmentalization is  
6 different and biotransformation systems are less developed. However, a high quality  
7 mollusc BCF may be used as a worst case estimate for a fish BCF in the absence of other  
8 data. BCF values determined for other invertebrates (e.g. algae) should not be used,  
9 since they are prone to high uncertainty (see Section [R.7.10.4.1](#)).

10 The ITS presented in Section [R.7.10.6](#). builds on these principles.

#### 11 **R.7.10.5.1 Concluding on suitability for Classification and Labelling**

12 All substances should be assessed for environmental hazard classification.  
13 Bioaccumulation potential is one aspect that needs to be considered in relation to long-  
14 term effects. For the majority of non-ionised organic substances, classification may be  
15 based initially on the log  $K_{ow}$  (estimated if necessary) as a surrogate, if no reliable  
16 measured fish BCF is available. Predicted BCFs are not relevant for classification  
17 purposes because the criteria for long-term aquatic hazard employ a cut off relating to  
18 log  $K_{ow}$ , when the preferred type of information, measured BCF on an aquatic organism  
19 is not available. In cases where the  $K_{ow}$  is not a good indicator of accumulation potential  
20 (see [Appendix R.7.10-3](#)), an *in vivo* test would usually be needed if a case for limited  
21 bioaccumulation cannot be presented based on other evidence (e.g. metabolism, etc.).  
22 High quality BCFs determined for non-fish species (e.g. blue mussel, oyster and/or  
23 scallop) may be used directly for classification purposes if no fish BCF is available.

#### 24 **R.7.10.5.2 Concluding on suitability for PBT/vPvB assessment**

25 Guidance on the suitability for PBT/vPvB assessment is provided in Chapter R.11 of the  
26 [Guidance on IR&CSA](#).

#### 27 **R.7.10.5.3 Concluding on suitability for use in Chemical Safety** 28 **Assessment**

29 Fish BCF and BMF values are used to calculate concentrations in fish as part of the  
30 secondary poisoning assessment for wildlife, as well as for human dietary exposure. A  
31 BMF for birds and mammals may also be relevant for marine scenarios (in the absence of  
32 actual data, a fish BMF measured in a dietary test can be used as a surrogate provided it  
33 is higher than the default). An invertebrate BCF may also be used to model a food chain  
34 based on consumption of sediment worms or shellfish. An assessment of secondary  
35 poisoning or human exposure via the environment will not always be necessary for every  
36 substance; triggering conditions are provided in Chapter R.16.

37 In the first instance, a predicted BCF may be used for first tier risk assessment. If the  
38 PEC/PNEC ratio based on worst case BCF or default BMF values indicates potential risks  
39 at any trophic level, it should first be considered whether the PEC can be refined with  
40 other data (which may include the adoption of specific risk management measures)  
41 before pursuing further fish tests. Such data may include:

- 42 • release information,

- 1 • fate-related parameters such as determination of more reliable log  $K_{ow}$  or  
2 degradation half-life (any uncertainty in the derived values should be taken  
3 into account in a sensitivity analysis).

4 In some circumstances, evidence from *in vitro* or mammalian tests may be used as part  
5 of a *Weight-of-Evidence* argument that metabolism in fish will with a high probability be  
6 substantial. This could remove the concern case-by-case, especially if a worst case  
7 PEC/PNEC ratio is only just above one. Such evaluations will require expert judgement.

8 Other issues may be relevant to consider and use in a refinement of secondary poisoning  
9 assessment is required. Experience relating to risk assessment of certain data rich  
10 chemicals indicate that such issues could relate to bioavailability of the substance in prey  
11 consumed by predators, feeding preference of predator in relation to selection of type of  
12 prey (e.g. fish, bivalves etc.), feeding range of predators etc. If possible more complex  
13 food web models and specific assessment types may be employed if scientifically  
14 justified. The inclusion of such considerations may provide a more robust basis for  
15 performing secondary poisoning assessment.

16 Depending on the magnitude of the PEC/PNEC ratio and the uncertainty in the  $PNEC_{oral}$ , it  
17 might also be appropriate in special circumstances to derive a more realistic  $NOEC_{oral}$   
18 value from a long-term feeding study with laboratory mammals or birds before  
19 considering a new fish BCF test. If further mammalian or avian toxicity testing is  
20 performed, consideration could also be given to extend such studies to include satellite  
21 groups for determination of the concentration of the substance in the animals during  
22 exposure (i.e. to measure BMF values for top predators).

23 If further data on fish bioaccumulation are considered essential, it may be appropriate in  
24 special cases to start with fish dietary studies to determine the assimilation coefficient  
25 and the biological half-life of the substance prior to estimating or determining the BCF.

26 Although field studies can give valuable 'real world' data on bioaccumulation  
27 assessments, they are resource intensive, retrospective and have many interpretation  
28 problems. Therefore, field monitoring as an alternative or supplementary course of  
29 action to laboratory testing is only likely to be necessary in exceptional cases, Active  
30 sampling of (top) predators should generally be avoided on ethical grounds. Instead,  
31 studies are likely to require non-lethal sampling methods (e.g. collection of animals that  
32 are found dead, droppings, infertile birds' eggs or biopsies of mammalian skin or  
33 blubber). Consequently, they will need careful design, and the sampled environment  
34 must be appropriate to the assessment.

#### 35 **R.7.10.6 Integrated Testing Strategy (ITS) for aquatic** 36 **bioaccumulation**

##### 37 **R.7.10.6.1 Objective / General principles**

38 The objective of the testing strategy is therefore to provide information on aquatic  
39 bioaccumulation in the most efficient manner so that animal usage and costs are  
40 minimised. In general, more information is needed when the available data suggest that  
41 the BCF value is close to a regulatory criterion (i.e. for classification and labelling, PBT  
42 assessment, and the BCF that may lead to a risk being identified in the chemical safety  
43 assessment).

### 1 **R.7.10.6.2 Preliminary considerations**

2 The first consideration should be the substance composition, the chief questions being: is  
3 the substance a non-ionised organic compound, and does it have well defined  
4 representative constituents? If the answer to these is no, then the use of  $K_{ow}$ - or QSAR-  
5 based estimation methods will be of limited help (see [Appendix R.7.10-3](#)). It is also  
6 important to have sufficient information on physico-chemical properties (such as vapour  
7 pressure, water solubility and  $K_{ow}$ ), since these will have a significant impact on test  
8 design as well as the potential for aquatic organisms to be exposed (e.g. a poorly soluble  
9 gas might not need to be considered further). It may be possible at this stage to decide  
10 whether the substance is unlikely to be significantly bioaccumulative (i.e.  $\log K_{ow} < 3$ ).  
11 Finally, if there is substantiated evidence that direct and indirect exposure of the aquatic  
12 compartment is unlikely, then this should be recorded as the reason why further  
13 investigation is not necessary.

### 14 **R.7.10.6.3 Testing strategy for aquatic bioaccumulation**

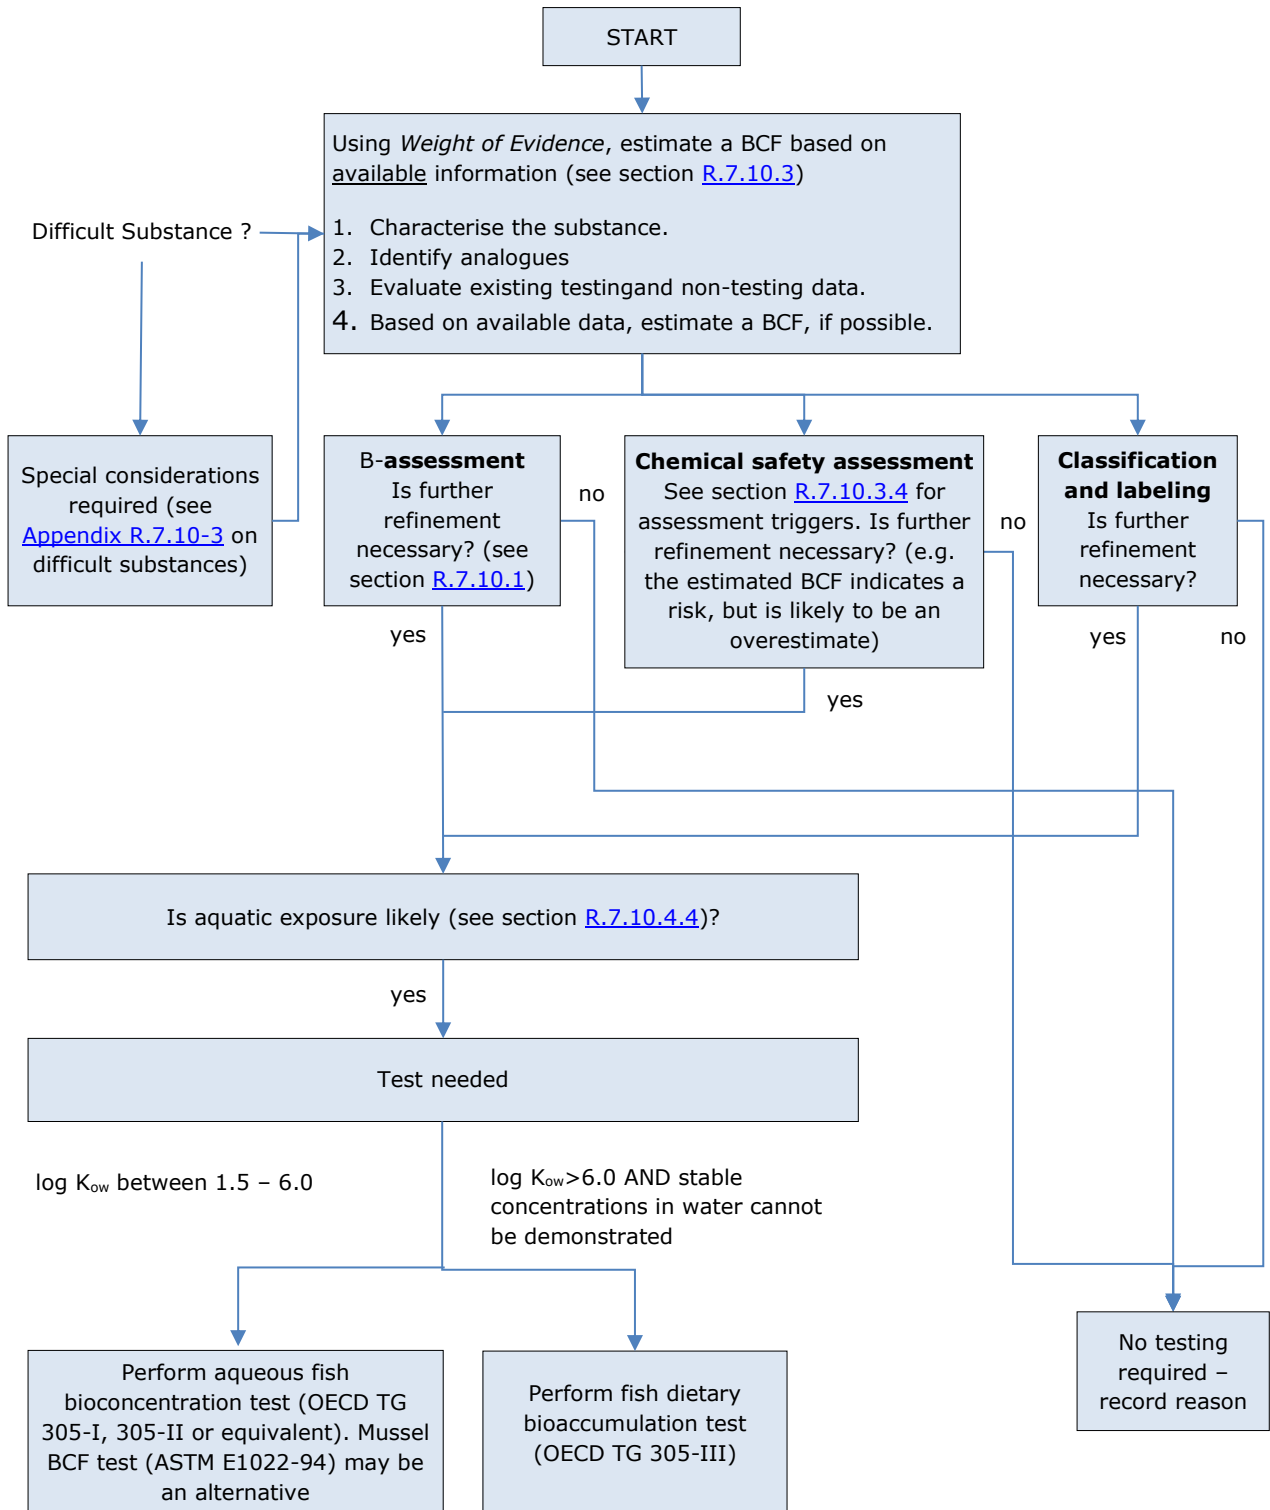

15 A strategy is presented in [Figure R.7.10—1](#) for substances made or supplied at 100 t/y.  
16 References are made to the main text for further information. The collection of  
17 bioaccumulation data might be required below 100 t/y to clarify a hazard classification or  
18 PBT properties in some cases. Furthermore, collection and/or generation of additional  
19 bioaccumulation data is required for the PBT/vPvB assessment in case a registrant  
20 carrying out the CSA cannot draw an unequivocal conclusion either (i) (“The substance  
21 does not fulfil the PBT and vPvB criteria”) or (ii) (“The substance fulfils the PBT or vPvB  
22 criteria”) on whether the bioaccumulation criteria in Annex XIII to REACH are met or not  
23 (see Chapter R.11 of the *Guidance on IR&CSA* for further details) and the PBT/vPvB  
24 assessment shows that additional information on bioaccumulation is needed for deriving  
25 one of these two conclusions.

26 It should be noted that in some cases risk management measures could be modified to  
27 remove the concern identified following a preliminary assessment with an estimated BCF  
28 (in case the substance is potentially PBT/vPvB, see Chapter R.11 of the [Guidance on](#)  
29 [IR&CSA](#) for further details). Alternatively, it may be possible to collect other data to  
30 refine the assessment (e.g. further information on releases, non-vertebrate toxicity  
31 (which could be combined with an accumulation test) or environmental fate). In such  
32 cases a tiered strategy could place the further investigation of aquatic bioaccumulation  
33 with fish in a subsequent step.

34 It should also be considered whether an invertebrate test is a technically feasible and  
35 cost-effective alternative approach to estimating a worst case fish BCF. If refinement of  
36 the BCF is still needed following the performance of such a test, a fish study may still be  
37 required.

38 It should be noted that the ITS does not include requirements to collect *in vitro* or field  
39 data. The use of *in vitro* data will continue to be a case-by-case decision until such time  
40 that these techniques receive regulatory acceptance. Field data might possibly be of  
41 relevance if further information needs to be collected on the biomagnification factor.  
42 Related to this is the need to consider the  $K_{oa}$  value for high  $\log K_{ow}$  substances (see  
43 [Section R.7.10.3.4](#)).

### 1 **R.7.10.8 Terrestrial Bioaccumulation**

2 Information on chemical accumulation in terrestrial organisms is important for wildlife  
3 and human food chain exposure modelling and PBT assessment as part of the chemical  
4 safety assessment. This report considers the data that can be gathered from test and  
5 non-test methods for earthworms and plants, since these can be related to a clear  
6 strategy and standardised test guidelines. Further, the accumulation in terrestrial food  
7 chains is addressed briefly. Information on accumulation in earthworms is used for the  
8 assessment of secondary poisoning, and it can also be a factor in decisions on long-term  
9 soil organism toxicity testing. Information on plant uptake is used to estimate  
10 concentrations in human food crops and fodder for cattle. For substances used in down  
11 the drain products, assessment of indirect exposure of the soil via sewage sludge is  
12 important.

13 Accumulation in other relevant media (e.g. transfer of a substance from crops to cattle  
14 to milk) is considered in Chapter R.16.

15 It is further noted that the concept of terrestrial bioaccumulation builds where relevant  
16 on the same one for the aquatic compartment, but the database underpinning the  
17 former is much smaller. Bioaccumulation assessments in the terrestrial compartment are  
18 more uncertain than similar ones for the aquatic compartment.

#### 19 **R.7.10.8.1 Defintitions and metrics used in terrestrial** 20 **bioaccumulation**

21 Uptake of a chemical by a soil-dwelling organism is a complex process determined by the  
22 properties of both the substance and the soil, the biology of the organism and climatic  
23 factors (UBA, 2003). For risk assessment, this complexity tends to be ignored, and the  
24 process is expressed in terms of simple ratios.

25 The bioaccumulation from soil to terrestrial species is expressed by the biota-to-soil  
26 accumulation factor, defined as:

$$27 \quad \text{BSAF} = \frac{C_o}{C_s}$$

28 where BSAF is the biota-soil accumulation factor (dimensionless),  $C_o$  is the chemical  
29 concentration in the whole organism (mg/kg wet weight),  $C_s$  is the chemical  
30 concentration in whole soil (i.e. pore water and soils) (mg/kg wet weight). Often the  
31 BSAF values are normalised to the lipid content of the organisms and the organic carbon  
32 content of the soil to obtain more informative results.

33 Alternatively, the concentration in the organism may be related to the concentration in  
34 soil pore water. The resulting ratio is a bioconcentration factor and is defined as:

$$35 \quad \text{BCF} = \frac{C_o}{C_{pw}}$$

36 where BCF is the bioconcentration factor (L/kg),  $C_o$  is the chemical concentration in the  
37 whole organism (mg/kg wet weight),  $C_{pw}$  is the chemical concentration in soil pore water  
38 (mg/L). Measurement of BCF is relevant only for certain cases, when accumulation from  
39 the porewater is expected to dominate over accumulation from ingestion of soil.

1 These partition coefficients can be used to estimate the concentration of a chemical in an  
2 organism living in contaminated soil.

3 The biomagnification factor (BMF) and the trophic magnification factor (TMF) are factors  
4 that are used to express the transfer of a substance in the terrestrial food chain. The  
5 biomagnification factor is defined as:

$$6 \quad \text{BMF} = \frac{C_{\text{predator}}}{C_{\text{prey}}}$$

7 where BMF is the biomagnification factor and  $C_{\text{predator}}$  and  $C_{\text{prey}}$  are the chemical  
8 concentration in the whole organism (mg/kg wet weight) of a predator and its prey. To  
9 obtain comparable results, the BMF is often normalized to the lipid content of both  
10 predator and prey.

11 The trophic magnification factor is obtained from the slope of the log-transformed  
12 normalised concentrations of organisms in the entire food chain as a function of trophic  
13 level of those organisms. The TMF is calculated as:

14

15

$$\text{TMF} = 10^{\text{slope}}$$

## 1 **R.7.10.8.2 Objective of the guidance on terrestrial bioaccumulation**

2 The aim of this document is to provide guidance to registrants on the assessment of all  
3 available data on a substance related to terrestrial bioaccumulation, to allow a decision  
4 to be made on the need for further testing (with earthworms or, where appropriate,  
5 plants).

## 6 **R.7.10.9 Information requirements for terrestrial bioaccumulation**

7 Data on terrestrial bioaccumulation are not explicitly referred to in REACH as a standard  
8 information requirement in Annexes VII-X, but it assumed that an exposure assessment  
9 for secondary poisoning and indirect exposure to humans via the environment will be a  
10 standard element of the chemical safety assessment at the level of 10 t/y or higher. The  
11 need to perform such an assessment will depend on a) substance properties and b)  
12 relevant emission and exposure (see Chapter R.16 for more details). If an assessment is  
13 required, this will involve an estimate of accumulation in earthworms and plants.

14 Section 9.3.4 of Annex X to REACH indicates that further information on environmental  
15 fate and behaviour may be needed for substances manufactured or imported in  
16 quantities of 1,000 t/y or higher, depending on the outcome of the chemical safety  
17 assessment. This may include a test for earthworm and/or plant accumulation.

18 Furthermore, if a registrant carrying out the chemical safety assessment (CSA) identifies  
19 in the PBT/vPvB assessment that a definitive conclusion cannot be derived, and the  
20 PBT/vPvB assessment shows that additional information on bioaccumulation is needed  
21 for deriving a conclusion, the necessary additional information must be provided by the  
22 registrant. This obligation applies for all  $\geq 10$  t/y registrations (see Chapter R.11 of the  
23 [Guidance on IR&CSA](#) for further details). In such a case, the only possibility to refrain  
24 from testing or generating other necessary information is to treat the substance "as if it  
25 is a PBT or vPvB" (see Chapter R.11 of the [Guidance on IR&CSA](#) for details).

26

## 27 **R.7.10.10 Available information on terrestrial bioaccumulation**

### 28 **Earthworm bioaccumulation test**

29 OECD TG 317 (OECD, 2010) is a standard test guideline for earthworms, which is  
30 applicable to stable neutral organic chemicals, metallo-organics, metals, and other trace  
31 elements. In principle, worms (e.g. *Eisenia fetida*) are exposed to the test substance in a  
32 well-defined artificial soil substrate or natural soil at a single test concentration that is  
33 shown to be non-toxic to the worms. After 21 days' (earthworms) or 14 days'  
34 (enchytraeids) exposure, the worms are transferred to a clean soil for a further 21 days  
35 (earthworms) or 14 days (enchytraeids). In both the uptake and elimination phases the  
36 concentration of the test substance in the worms is monitored at several time points.

37 When steady state is reached, the steady state biota-soil accumulation factor ( $BSAF_{ss}$ ) is  
38 calculated, while the kinetic biota-soil accumulation factor ( $BSAF_k$ ) is calculated from the  
39 uptake and depuration rate constants.

40 The contribution of the gut contents to the total amount of substance accumulated by  
41 the worms may be significant, especially for substances that are not easily taken up in

1 tissues but strongly adsorb to soil. The worms are therefore allowed to defecate before  
2 analysis, which gives more information on the real uptake of the substance (although  
3 trace amounts sorbed to soil may still remain in the worms even after defecation). This  
4 is to obtain a measure of real uptake of the substance by the worms, which is important  
5 for a bioaccumulation assessment. However, if secondary poisoning is considered  
6 worms are ingested with gut content and this should be accounted for in the exposure  
7 assessment. For the secondary poisoning assessment, it should be considered whether  
8 the test concentration used in the study was environmentally relevant. If a higher test  
9 concentration was used, it may be over-conservative to use the BSAF which includes the  
10 gut contents with contaminated soil.

11 This is especially important for worms sampled during the uptake phase, which have  
12 contaminated soil as gut contents. As soon as the contaminated gut contents are  
13 replaced by clean soil in the depuration phase, defecation is no longer necessary before  
14 chemical analysis (in that case, the weight of the gut contents is estimated to account  
15 for dilution of the test item concentration by uncontaminated soil).

16 ASTM E1676-04 describes a similar method for bioaccumulation testing with the annelids  
17 *Eisenia fetida* and *Enchytraeus albidus* over periods up to 42 days (ASTM, 2004).

18 Relevant data might also be available from field studies or earthworm toxicity studies  
19 (e.g. if tissue concentrations are measured). The suitability of data derived from such  
20 studies to provide meaningful information on a substance's bioaccumulation potential,  
21 has to be assessed on a case-by-case basis.

## 22 **(Q)SAR models for earthworms**

23 The model of Jager (1998) is recommended as a reasonable worst case for an initial  
24 assessment of the earthworm bioconcentration factor, and provides a description of this  
25 tool. The only input term required is the octanol-water partition coefficient ( $K_{ow}$ ), and an  
26 application range of  $\log K_{ow}$  0-8 is advised. It was developed from a data set containing  
27 chlorobenzenes, pesticides, PCBs, PAHs, and chlorophenols. The model is limited to  
28 mostly neutral organic compounds and does not explicitly consider biomagnification or  
29 biotransformation. With due consideration it may be applicable to certain ionisable  
30 organics. Due to the narrow range of chemical groups within the model, it should be  
31 recognised that the model predictions have some limitations.

32 In cases where the  $K_{ow}$  is not a good indicator of bioconcentration (e.g. for ionic organic  
33 substances, metals or other substances that do not preferentially partition to lipids),  
34 either an alternative model for that specific substance or class of substances should be  
35 used, or an empirical BCF estimated from structural analogues. For example, Smit *et al.*  
36 (2000) provide a review of different equations for a limited number of metals.

## 37 **Comparison of earthworms with benthic organisms**

38 The results of bioaccumulation tests with suitable sediment-dwelling invertebrate species  
39 (e.g. the oligochaete *Lumbriculus variegatus*) may provide useful comparative  
40 information that can be used in a *Weight-of-Evidence* approach, if available. Further  
41 information on this test is given in the aquatic accumulation chapter. However, caution is  
42 warranted as a thorough comparison of bioaccumulation data for terrestrial and benthic  
43 species is currently lacking.

## 1 **Terrestrial plants**

2 Plants and crops can be contaminated by the transfer of chemicals from:

- 3 • soil (including solids and pore water) via the roots and translocation,
- 4 • air via the gas phase or particle deposition, and
- 5 • soil particles that splatter and stick on the foliage.

6 The need to assess these routes is determined by the approach adopted for the chemical  
7 safety assessment (see Chapter R.16).

## 8 **Plant uptake test**

9 Currently, no standardized test guidelines are specifically designed to develop  
10 bioaccumulation metrics (e.g., BCF, BAF) in plants (Gobas et al 2016). For simplicity in  
11 the discussion that follows, the term BAF will be used as a surrogate to represent all  
12 potential measures of bioaccumulation that have been used with plants.

13 A guideline that addresses plant uptake, translocation, and metabolism of chemicals  
14 (e.g. USEPA 2012) could provide data useful in determining whether a chemical  
15 accumulates in plants. The USEPA test guideline (2012) OCSPP 850.4800 outlines  
16 procedures for conducting a mass balance study of the distribution of a chemical in  
17 environmental matrices and different components of the plant under root or foliar  
18 exposure for use in determining human and livestock food safety. Although these  
19 guidelines were not specifically designed to assess bioaccumulation in plants, they do  
20 evaluate the ability of pesticides to be taken up by and translocate throughout plants,  
21 using a maximum exposure scenario, or characterize metabolic or degradation pathways  
22 to identify residues of concern.

23 The data collected could allow for the calculation of a bioaccumulation metric(s) based  
24 on the ratio of the concentration of the chemical in the plant relative to the concentration  
25 in the relevant environmental matrices, provided steady-state conditions are  
26 approximated. During the conducting of the test, the method of exposure (i.e. spraying,  
27 dusting, biosolids-amended soil, soil spiking), route of exposure (i.e. leaf and/or root),  
28 quantification of exposure, and characteristics of plant growth matrices would need to be  
29 considered carefully for the determination of a realistic bioaccumulation metric.

30 The guideline permits exposure via foliage as well as roots (and consequently provides  
31 advice on how to handle gaseous and volatile substances). Three test concentrations are  
32 recommended, with the number of replicates depending on the method of chemical  
33 analysis (fewer being required if radioanalysis is used). The test duration and number of  
34 plants selected are not specified, but should provide sufficient biomass for chemical  
35 analysis. Several species are suggested, including food crops and perennial ryegrass.

36 In principle, in case the test chemical concentrations are measured in the environmental  
37 matrices, the collected data could allow for the calculation of a bioaccumulation  
38 metric(s). In order for this metric to be realistic, the method, route and quantification of  
39 exposure as well as characteristics of plant growth matrices have to be considered  
40 carefully.

1 Relevant data might also be available from non-guideline studies, field studies or plant  
2 toxicity studies (e.g. if tissue concentrations are measured), as well as from guideline  
3 toxicity studies with terrestrial plants, for which additional chemical analysis in the plants  
4 has been performed, e.g. according to OECD TG 208 (OECD, 2006).

### 5 **(Q)SAR models for plants**

6 Several models are possibly useful for estimating chemical accumulation in plants. A  
7 review of these models has been made. The validation of all models is hampered by the  
8 lack of experimental standardised data in plants (Gobas *et al.*, 2016).

9 For most of the models, the only input required is the  $K_{ow}$ , but additional simple physico-  
10 chemical properties (e.g. molecular weight, vapour pressure and water solubility) are  
11 needed for some. As discussed in Gobas *et al.* (2016) and elsewhere, the applicability  
12 domain of the current plant models may be limited due to insufficient test data for a  
13 broad range of chemistry (i.e. range of  $K_{ow}$ , pKa, MW) and non-standardised testing.

### 14 **Biomagnification in the terrestrial food chain**

15 The default terrestrial food chain for secondary poisoning assessment is defined as soil -  
16 earthworm - earthworm eating bird/mammals (REACH R16 section 16.6.7.2).

17  
18 Similarly to the aquatic food chain, in the terrestrial food chain, accumulation in higher  
19 trophic levels may occur as well, where small birds and mammals serve as prey for  
20 terrestrial predators, such as raptors and mustelids (Jongbloed *et al.*, 1994, Armitage *et*  
21 *al.*, 2007). This would lead to a default example terrestrial food chain that is defined as:

22  
23 soil → earthworm/plant → worm or plant-eating birds or mammal → predator

24  
25 Usually, to assess this type of information only field data or modelling data are available  
26 that assess the accumulation in birds and mammals in the terrestrial environment. More  
27 information on the interpretation of field data or modelling data is given below.

28

### 29 **QSARs for terrestrial food chain**

30 Several models exist to estimate the biomagnification in terrestrial avian and  
31 mammalian species and food webs. Models have been developed for neutral, nonionic  
32 substances undergoing passive transport. These models are based on the  $K_{ow}$  and  $K_{oa}$  of  
33 the chemical. Depending on the food web modelled, substances have the potential to  
34 biomagnify if the  $\log K_{oa} > \sim 5-6$  in combination with a  $\log K_{ow} > \sim 2$ . Models for  
35 ionogenic substances and substances that are not accumulating by hydrophobic  
36 partitioning are lacking. There is further need to develop estimation methods for the rate  
37 of biotransformation and dietary assimilation efficiencies for all levels of the terrestrial  
38 food web (Gobas *et al.*, 2016).

### 39 **Toxicokinetic data**

40 Toxicokinetic studies in air-breathing organisms may provide useful information on  
41 bioaccumulation in particular for substances with a combination of  $\log K_{ow} > 2$  and  $\log K_{oa}$   
42  $> 4.5$ . For further information, see Section 0 and Section [R.7.12](#).

43

1 **R.7.10.11 Evaluation of available information on terrestrial**  
2 **bioaccumulation**

3 **Test data on terrestrial bioaccumulation**

4 Experience with the evaluation of specific earthworm and plant bioaccumulation tests is  
5 limited, since they are rarely requested for industrial and consumer chemicals. Jager *et*  
6 *al.* (2005) provide some information on earthworm bioassays. Data obtained using  
7 standard methods are preferred. Non-guideline studies in particular need to be evaluated  
8 with care. Factors to be considered in general include:

- 9 • Where possible, the exposure duration should be sufficient to enable steady  
10 state to be achieved, in particular for highly hydrophobic substances (e.g. log  
11  $K_{ow} > 6$ ). However, for most root crops, and most hydrophobic compounds, it  
12 may take much longer than the growth period to reach steady state. In such  
13 cases, crops should be monitored over their entire growing season.
- 14 • The test concentration should be ecologically relevant and should not cause  
15 significant toxic effects on the organism, while it also needs to be above the  
16 limits of quantification.
- 17 • Tissue sampling for plants should be relevant for the substance of interest (in  
18 terms of its expected distribution in root, foliage, etc.), and the requirement  
19 of the exposure assessment (e.g. vegetables should be considered whole  
20 rather than peeled, etc.).
- 21 • If plant root is the tissue of interest, there are several factors to consider. Pot  
22 sizes should not restrict root development. The test species should be a  
23 relevant food crop with a lipid-rich surface layer. The surface area-volume  
24 ratio may be important (i.e. is the surface area large in relation to the volume  
25 of the root?) The use of fast-growing miniature varieties may lead to bias,  
26 since transfer from the peel to the core of the root tends to be a slow process  
27 (Trapp, 2002).
- 28 • Sometimes plants are grown hydroponically to allow for simplified uptake and  
29 elimination phase logistics. However, this is not an environmentally relevant  
30 mode of exposure and a chemical's ability to bioaccumulate can vary  
31 significantly as compared with a natural growth substrate (Hoke *et al.*, 2015;  
32 Karnjanapiboonwong *et al.*, 2011).
- 33 • In addition to organic carbon content, pH and soil texture are additional  
34 parameters that have been shown to cause variability in bioaccumulation in  
35 plants. As such, these have to be taken into account when selecting the type  
36 and number of test soils (Hoke *et al.*, 2015).
- 37 • Bioaccumulation also varies across plant species (e.g. Huelster *et al.*, 1994)  
38 and plant cultivars (Inui *et al.*, 2008).
- 39 • It is important to ensure that the organism is cleaned and (for worms)  
40 allowed to void its gut contents prior to analysis (since small amounts of  
41 retained contaminated soil could give false results). The inclusion of a

- 1 elimination phase with clean soil as prescribed in OECD TG 317 will help to  
2 assess the influence of gut content on the organism's concentration.
- 3 • Analytical methods should be sensitive enough to detect the substance in both  
4 the soil and the organism tissue, and may require radiolabelled substances. It  
5 should be noted that radioanalysis does not by itself give information about  
6 the amount of intact chemical within the organism, and preferably it should be  
7 supported by parent compound analysis so that the contribution of  
8 metabolites can be assessed.
  - 9 • Whole soil tests tend to provide a BSAF, which is not very informative as  
10 indicator of bioaccumulation potential since it also reflects sorption behaviour.  
11 A better indicator would be the BCF based on the freely dissolved  
12 (bioavailable) soil pore water concentration. Ideally, this should be done using  
13 direct analytical measurement (which may involve sampling devices such as  
14 SPME fibres (e.g. Van der Wal *et al.*, 2004)). If no analytical data are  
15 available, the pore water concentration may be estimated using suitable  
16 partition coefficients, although it should be noted that this might introduce  
17 additional uncertainty to the result.
  - 18 • The data may need to be transformed for use in a standardised way in the  
19 exposure assessment. For example:
    - 20 - Where possible, accumulation data should be normalised to the default  
21 lipid content of the organism. If lipid is not expected to play an  
22 important role in partitioning behaviour, such normalisation might not  
23 be appropriate. If applicable a different kind of normalisation could be  
24 considered (e.g. on dry weight or protein content).
    - 25 - If data are available regarding the variation in accumulation with soil  
26 type, etc., this should be described. If the organic carbon content of  
27 the test soil differs from the default soil used to derive the PEC (e.g. if  
28 the soil has been amended with sewage sludge), data should be  
29 normalised to the default organic matter/carbon content, if valid. This  
30 is relevant for neutral organic compounds; for metals and ionic or polar  
31 organic substances, soil parameters other than organic carbon may be  
32 more important and the validity of normalisation should be  
33 investigated first.
- 34 In the case of worms, the total amount of the substance present in the worm (i.e. tissue  
35 plus gut contents) is still a relevant parameter for secondary poisoning, because a  
36 predator will consume the whole worm. The fraction of the substance that is sorbed to  
37 the gut content can be estimated by assuming a fixed weight percentage of the gut  
38 content. The fraction of the gut content is by default set to  $0.1 \text{ kg}_{\text{dry weight soil}}/\text{kg}_{\text{wet weight}}$   
39  $\text{worm}$  (Jager *et al.*, 2003; Jager, 2004).
- 40 An ILSI/HESI terrestrial bioaccumulation workshop was held in January 2013 and a  
41 publication by Hoke *et al.* (2016) presents a review of the application of laboratory-  
42 based approaches for terrestrial bioaccumulation assessment of organic chemicals.
- 43 Evaluation of toxicokinetic data for the purpose of bioaccumulation assessment is further  
44 explained in Section 0 and Section [R.7.12](#).

## 1 **Non-testing data on terrestrial bioaccumulation**

2 The use of QSARs will be mainly determined by the guidance for the chemical safety  
3 assessment as described by the report on exposure tools, which provides an evaluation  
4 of the recommended models, including their applicability domain. If a substance is  
5 outside of the applicability domain, then the results should be used with caution in the  
6 assessment. The use of any model should be justified on a case-by-case basis.

7 The 2013 ILSI/HESI terrestrial bioaccumulation workshop resulted in a publication by  
8 Gobas *et al.* (2016) which presents a review of the current terrestrial bioaccumulation  
9 models and their merits and limitations. In this review models for accumulation in  
10 terrestrial food chains are presented next to the above mentioned models for terrestrial  
11 invertebrates and plants. It should be noted that also the models for assessing  
12 accumulation through the terrestrial food chain are mainly restricted to neutral, nonionic  
13 organic chemicals. In addition to  $K_{ow}$  another important physicochemical property for  
14 terrestrial bioaccumulation in air-breathing organisms is the octanol-air partition  
15 coefficient ( $K_{oa}$ ).

16 General guidance on read-across and categories is provided in the report on aquatic  
17 accumulation (see Section [R.7.10.3.2](#)).

18

### 19 **R.7.10.11.1 Field data**

20 General guidance for the evaluation of data from field studies is provided in the report on  
21 aquatic accumulation (see Section [R.7.10.3.3](#)). The exposure scenario for the chemical  
22 safety assessment considers spreading of sewage sludge to land over a 10-year period,  
23 and consequently the exposure history of the soil should be described. Some of the  
24 factors described in Section [R.7.10.4.3](#) are also relevant.

25 As noted previously, a terrestrial bioaccumulation workshop was sponsored by ILSI/HESI  
26 in 2013 and a publication by van den Brink (2016) discusses the use of field studies to  
27 examine the potential bioaccumulation of chemicals in terrestrial organisms. In this  
28 review a comparison with aquatic bioaccumulation is made. The differences with the  
29 aquatic environment and the special points of attention for the terrestrial environment  
30 with regard to the derivation and use of experimentally derived endpoints from field data  
31 are highlighted.

32

### 33 **R.7.10.11.2 Exposure considerations for terrestrial bioaccumulation**

34 An assessment of secondary poisoning or human exposure via the environment is part of  
35 the chemical safety assessment. Triggering conditions are provided in Chapter R.16 of  
36 the [Guidance on IR&CSA](#).

37

### 38 **R.7.10.12 Conclusions for terrestrial bioaccumulation**

39 There is a hierarchy of preferred data sources to describe the potential of a substance to  
40 bioaccumulate in terrestrial species, as follows:

- 1           • In general, preference is given to reliable measured BCF data on the  
2 substance itself in terrestrial plants or earthworms. It should be noted that  
3 experimental data on highly lipophilic substances (e.g. with log  $K_{ow}$  above 6)  
4 will have a much higher level of uncertainty than BCF values determined for  
5 less lipophilic substances. A BSAF might be an alternative measure.
- 6           • Next in order of preference comes reliable measured BCF data from the  
7 sediment worm *Lumbriculus variegatus* as a surrogate for earthworm data.  
8 Although differences are not expected to be large in principle, comparative  
9 information is lacking. Read-across on BCF data from a sediment organism to  
10 a terrestrial organism should therefore be made on a case-by-case basis,  
11 taking account of any differences in organic carbon and pore water contents  
12 between sediment and soil.
- 13          • Field data might also be useful at this *stage* as part of a *Weight-of-Evidence*  
14 argument (these require careful evaluation and will not be available for the  
15 majority of substances). Apart from field data on accumulation in terrestrial  
16 plants and invertebrates also data on biomagnification in terrestrial food  
17 chains should be taken into account.
- 18          • Toxicokinetic data may also be utilised, case-by-case, in the bioaccumulation  
19 assessment and should be addressed in the assessment when accumulation in  
20 air-breathing organisms is likely to be more pronounced than in water  
21 breathing organisms. See further details in Section [R.7.10.12](#).
- 22          • The next line of evidence concerns data from non-testing methods.
- 23          • Other lines of evidence concerns indications and rules based on physico-  
24 chemical properties. Nevertheless, the log  $K_{ow}$  is a useful screening tool for  
25 many substances, and it is generally assumed that non-ionised organic  
26 substances with a log  $K_{ow}$  below 3 (4, GHS) are not significantly  
27 bioaccumulative for the aquatic environment. No such triggers can be given  
28 for the terrestrial environment. In addition, log  $K_{oa}$  >5 is a useful trigger to  
29 assess whether biomagnification in the terrestrial food chain might occur.

30 In principle, the available information from testing and non-testing approaches, together  
31 with other indications such as physico-chemical properties, must be integrated to reach a  
32 conclusion that is fit for the regulatory purpose regarding the bioaccumulation of a  
33 substance. A scheme is presented in the report for aquatic accumulation, and the broad  
34 principles are the same for terrestrial species. In summary:

- 35           • Make a preliminary analysis of bioaccumulation potential based on the  
36 structure and physico-chemical properties of the substance, as well as  
37 information about its degradation products in the environment. It may be  
38 possible at this stage to decide that the substance is unlikely to be  
39 significantly bioaccumulated.
- 40           • Evaluate any existing *in vivo* data, including field data if available.
- 41           • Identify possible analogues, as part of a group approach if relevant.

- 1           • Evaluate non-testing data (e.g. QSARs, including whether  $K_{ow}$  and  $K_{ow}$ -based  
2           models are relevant, and read-across, etc.).
- 3           • Weigh the different types of evidence and examine whether it is possible to  
4           reach a conclusion on terrestrial bioaccumulation. Difficulties in reaching a  
5           conclusion on the BAF, and/or BMF may indicate the need for further testing.

6 It should be noted that if a substance has a measured fish BCF that is significantly lower  
7 than predicted by QSAR, it cannot be concluded that the earthworm BCF will also be  
8 lower than the predicted fish value. This is because biotransformation processes in  
9 particular are more extensive in fish than earthworms (few compounds are appreciably  
10 biotransformed by earthworms,

11

### 12 **R.7.10.12.1 Concluding on suitability for Classification and Labelling**

13 Data on accumulation in earthworms and plants are not used for classification and  
14 labelling.

### 15 **R.7.10.12.2 Concluding on suitability for PBT/vPvB assessment**

16 For judging the suitability of the information for PBT/vPvB assessment, see guidance in  
17 Chapter R.11 of the [Guidance on IR&CSA](#).

### 18 **R.7.10.12.3 Concluding on suitability for use in Chemical Safety 19 Assessment**

20 In general, predicted BSAF (or pore water BCF) and BMF values (whether from QSAR or  
21 read-across) can be used for the initial assessment of secondary poisoning and human  
22 dietary exposure. If a prediction is not possible, measured BSAF (e.g. OECD TG 317)  
23 data will be necessary at the 1,000 t/y level.

24

### 25 **R.7.10.13 Integrated testing strategy (ITS) for terrestrial 26 bioaccumulation**

#### 27 **R.7.10.13.1 Objective / General principles**

28 The objective of the testing strategy is to provide information on terrestrial  
29 bioaccumulation in the most efficient manner so that costs are minimised. In general,  
30 test data will only be needed at the 1,000 t/y level, if the chemical safety assessment  
31 identifies the need for further terrestrial bioaccumulation information. Furthermore,  
32 collection and/or generation of additional terrestrial bioaccumulation data are required  
33 for the PBT/vPvB assessment in all cases where a registrant carrying out the CSA cannot  
34 derive a definitive conclusion based on aquatic accumulation data, either (i) ("The  
35 substance does not fulfil the PBT and vPvB criteria") or (ii) ("The substance fulfils the  
36 PBT or vPvB criteria") in the PBT/vPvB assessment, and the PBT/vPvB assessment shows  
37 that additional information on terrestrial bioaccumulation would be needed for deriving  
38 one of these two conclusions. This obligation applies for all  $\geq 10$  t/y registrations (see  
39 Chapter R.11 of the [Guidance on IR&CSA](#) for further details).

### 1 **R.7.10.13.2 Preliminary considerations**

2 If predicted BSAF and BMF values indicate potential risks for either wildlife or humans,  
3 the need for further terrestrial bioaccumulation testing should be considered as part of  
4 an overall strategy to refine the PEC with better data, including:

- 5 • more realistic release information (including risk management  
6 considerations);
- 7 • other fate-related parameters such as determination of more reliable soil  
8 partition coefficients (which may allow a better estimate of the soil pore water  
9 concentration) or degradation half-life.

10 These data might also be needed to clarify risks for other compartments, and a  
11 sensitivity analysis may help to identify the most relevant data to collect first.

12 In addition, if further sediment organism bioaccumulation or soil organism toxicity tests  
13 are required, it may be possible to gather relevant data from those studies.

14 Depending on the magnitude of the risk ratio and the uncertainty in the effects data, it  
15 might also be appropriate in some circumstances to derive a more realistic NOAEL value  
16 from a long-term feeding study with laboratory mammals or birds, although this would  
17 not usually be the preferred option.

### 18 **R.7.10.13.3 Testing strategy for terrestrial bioaccumulation**

19 In general, the octanol-air partition coefficient ( $K_{oa}$ ) and octanol-water partition  
20 coefficient ( $K_{ow}$ ) can be used as the initial input for terrestrial bioaccumulation models at  
21 a screening level for most neutral organic substances.

22 If the substance is outside the domain of the models, and a BSAF and BMF cannot be  
23 established by other methods (such as analogue read-across or derived from field data),  
24 a test may be needed at the 1,000 t/y level. Similarly, if a risk is identified that is not  
25 refinable with other information, a test will usually be necessary.

26 Standard test guideline studies are preferred. The choice of test will depend on the  
27 scenario that leads to a risk, and the test species should reflect the specific route of  
28 uptake that may be expected from the properties of the individual substance under  
29 consideration. For example, where a model predicts the highest concentration to be in  
30 roots, the test species would be a relevant food crop.

31 Field monitoring might be an alternative or supplementary course of action to laboratory  
32 testing in special cases, especially for more hydrophobic substances that may take a  
33 long time to reach steady state. This will not be a routine consideration, because of the  
34 difficulty in finding soils that may have had an adequate exposure history.

1 **R.7.10.15 Mammalian toxicokinetic data in bioaccumulation**  
2 **assessment**

3 Mammalian toxicokinetic studies may provide useful information in a *Weight-of-Evidence*  
4 approach for bioaccumulation assessment. Metrics to consider include:

- 5 • metabolic capacity/rate constants
- 6 • affinity for lipid or blood-rich tissues, which could include the volume of  
7 distribution,  $V_D$  (a parameter that quantifies the distribution of a substance  
8 throughout the body after oral dosing; it is defined as the volume in which a  
9 substance would need to be homogeneously distributed to produce an  
10 observed blood concentration. If there is significant distribution into lipids the  
11  $V_D$  will be increased (although this may also be caused by renal and liver  
12 failure).
- 13 • the time taken to reach a steady-state (plateau) concentration in tissues, and
- 14 • uptake efficiency and clearance, and elimination rates/half-lives.

15 Standardised test methods (e.g. OECD TG 417 Toxicokinetics) are not widely used for  
16 deriving toxicokinetic data and therefore particular attention needs to be paid in the  
17 evaluation of such data to the sources of variation and their impact on the results.

18 Physiologically-based pharmacokinetic/toxicokinetic models (PBPK/PBTK) may support or  
19 expand the understanding of the toxicokinetic behaviour of a substance and their use  
20 should be considered, where a model applicable for the substance is available. For  
21 further information, see the IPCS/WHO project document on the PBPK models in risk  
22 assessment (2010).

23 Principles presented in OECD TG 417 Toxicokinetics should be as far as possible applied  
24 where relevant. When using elimination information the following aspects should be  
25 addressed as minimum:

- 26 • Species, age and gender of a test subject. Elimination rates/half-lives can vary  
27 between age and gender causing the need for half-life values to be determined  
28 for subgroups in the same species (Ng and Hungerbuhler, 2014).
- 29 • Sample type. Conventional practice to retrieve elimination data is to measure the  
30 concentration of a substance in serum, plasma or whole blood. In addition, urine,  
31 faeces, various tissue and organ specific data, and combination of such samples  
32 are frequently available.
- 33 • Study approach. Tests are usually conducted either using experimental (e.g.  
34 laboratory animal tests) or observational (e.g. human biomonitoring) approaches.
- 35 • Exposure aspects and dosing scheme. Exposure route(s), level, duration (short  
36 term/long term) and dosing scheme (single, episodic or continuous) should be  
37 addressed to define the overall scenario of a study. Results from studies  
38 conducted using ongoing exposure (intentional or unintentional) and single or  
39 repeated doses should all be reported and interpreted in a differentiating manner.  
40 Biomonitoring studies without or with only very limited and/or uncertain exposure  
41 information might call for estimation of likely exposure levels, routes,

1 duration/frequency and may due to high uncertainty not be particular useful as a  
2 single decision element in bioaccumulation assessments. A prerequisite for  
3 calculation of an elimination half-life is that the elimination pattern is shown to  
4 obey first-order kinetics or at least not deviate significantly from first order  
5 kinetics (pseudo-first-order kinetics). In case an elimination rate has been  
6 obtained from a study where exposure cannot be excluded, presentation of  
7 elimination half-lives needs to be coupled with explanation of the influence of  
8 continuing exposure to the results and a justification of why it can be assumed  
9 that the elimination follows (approximately) first-order kinetics.

- 10 • Descriptors of elimination half-life. The terminology used in the currently  
11 available studies is unfortunately not fully standardised. Applied toxicokinetic  
12 models and terminology (e.g. description of what is meant in a particular study  
13 by “half-life”, “apparent half-life” or “intrinsic half-life”) should be reported in  
14 detail. For the appropriate use of terminology, see Nordberg, Duffus and  
15 Templeton (2004).
- 16 • Analytical methods for detection and quantification (including sampling and  
17 extraction methods when relevant) of the substance concerned. Indicate whether  
18 direct detection or indirect detection by means of isotopic labels (e.g. radiocarbon  
19 C-14) was used. Report statistical methods applied for data analysis. Elimination  
20 half-lives are usually presented as arithmetic or geometric means, medians or  
21 ranges. All reported values, including the ranges, should be presented.

22 Finally, mammalian toxicokinetic information should be evaluated on a case-by-case  
23 basis as the current limited experience in their use in bioaccumulation assessment does  
24 not yet warrant further specification in this Guidance. See also Section [R.7.12](#) on  
25 toxicokinetic data.

26

27

### 1 **R.7.10.16 Avian Toxicity**

2 Information on (long-term) avian toxicity only needs to be considered for substances  
3 supplied at 1,000 t/y or more (Section 9.6.1 of Annex X to REACH). The data are used to  
4 assess the secondary poisoning risks to predators following chronic exposure to a  
5 substance via the fish and earthworm food chains<sup>5</sup>. Given that mammalian toxicity is  
6 considered in detail for human health protection, the need for additional data for birds  
7 must be considered very carefully – new tests are a last resort in the data collection  
8 process. However, birds are fundamentally different from mammals in certain aspects of  
9 their physiology (e.g. the control of sexual differentiation, egg laying, etc.), and so  
10 mammalian toxicity data are of limited predictive value for birds. This document  
11 describes how to assess information that already exists, and the considerations that  
12 might trigger new testing with birds.

13 It should be emphasised that there is a marked lack of relevant data available for  
14 industrial and consumer substances, and further research could be performed to:

- 15 • establish relative sensitivities of birds and mammals following chronic  
16 exposures,
- 17 • establish the validity of read-across arguments between structurally related  
18 substances,
- 19 • investigate *in vitro* approaches for birds, and
- 20 • identify structural alerts for chronic avian toxicity.

21 The guidance should therefore be reviewed as more experience is gained.

22 Readers should also refer to guidance related to the mammalian toxicokinetics (see  
23 Section [R.7.12](#)), repeated dose toxicity (see Section R.7.5 in Chapter R.7a of the  
24 [Guidance on IR&CSA](#)) and reproductive toxicity (see Section R.7.6 in Chapter R.7a of the  
25 [Guidance on IR&CSA](#)) endpoints for further relevant information.

#### 26 **R.7.10.16.1 Definition of avian toxicity**

27 The aim of an avian toxicity test is to provide data on the nature, magnitude, frequency  
28 and temporal pattern of effects resulting from a defined exposure regime (Hart *et al.*,  
29 2001). The three standard avian tests typically measure:

- 30 • lethal and delayed effects of short-term oral exposures (lasting minutes to  
31 hours, representing gorging behaviour, diurnal peaks in feeding (e.g. dawn  
32 and dusk) and products which depurate or dissipate very rapidly);
- 33 • lethal effects of medium-term dietary exposures (lasting hours to days,  
34 representing scenarios with relatively high exposures over several days); or

---

<sup>5</sup> Inhalation tests with birds are not considered necessary for industrial and consumer chemicals, since outdoor air concentrations are unlikely to exceed limits that will be set to protect human health (and other vertebrates by assumption). Dermal toxicity tests do not need to be considered for similar reasons.

- 1           • chronic lethal and reproductive effects of long-term dietary exposures (lasting  
2           up to 20 weeks).

3 Exposures are expressed in terms of either a:

- 4           • *concentration* of the substance in the food consumed by the birds (e.g.  
5           milligrams (mg) of test substance per kilogram (kg) of food<sup>6</sup>), or  
6           • *dose* expressed relative to body weight (e.g. mg test substance/kg body  
7           weight (per day, if more than a single exposure)).

8 The main results from an avian toxicity study include:

- 9           • the limit dose at which no mortality occurs (LD<sub>0</sub>);  
10          • a median lethal dose or concentration, at which 50% of birds die (LD(C)<sub>50</sub>);  
11          • a 'no observed effect' level, at which no effects of specified type occur, or a  
12          concentration at which either a defined level of effect is seen in x% of tested  
13          individuals, or an average deviation of x% is seen when compared to the  
14          untreated control (EC<sub>x</sub>); and  
15          • a statement of the type and frequency of effects observed in a specified  
16          exposure scenario (e.g. in a field study).

17 Other types of information may include the slope of a dose-response relationship, 95%  
18 confidence limits for the median lethal level and/or slope, and the time at which effects  
19 appear.

#### 20 **R.7.10.16.2 Objective of the guidance on avian toxicity**

21 Avian toxicity data are used in the assessment of secondary poisoning<sup>7</sup> risks for the  
22 aquatic and terrestrial food chains in the CSA. In the context of PBT/vPvB assessment  
23 (see Section [R.7.10.20](#)), avian toxicity data cannot be directly (numerically) compared  
24 with the T criterion (see Section 1.1.3 of Annex XIII to REACH). However, reprotoxicity  
25 studies or other chronic data on birds, if they exist, should be used in conjunction with  
26 other evidence of toxicity as part of a weight-of-evidence determination to conclude on  
27 substance toxicity (a NOEC ≤ 30 mg/kg food in a long term bird study should in this  
28 context be considered as a strong indicator of fulfilment of the T criterion).

#### 29 **R.7.10.17 Information requirements for avian toxicity**

30 Annex X to REACH indicates that information on long-term or reproductive toxicity to  
31 birds should be considered for all substances manufactured or imported in quantities of

---

<sup>6</sup> Units of mg/kg may also be expressed as parts per million (ppm).

<sup>7</sup> Secondary poisoning concerns the potential toxic impact of a substance on a predatory bird or mammal following ingestion of prey items (i.e. fish and earthworms) that contain the chemical. Accumulation of chemicals through the food chain may follow many different pathways along different trophic levels. This assessment is required for substances for which there is an indication for bioaccumulation potential ([Appendix R.7.10-3](#)).

1 1,000 t/y or more. Since this endpoint concerns vertebrate testing, Annex XI to REACH  
2 also applies, encouraging the use of alternative information. Although not listed in  
3 column 2 of Annex X to REACH, there are also exposure considerations (see Section  
4 [R.7.10.19.4](#)).

5 Although not specified at lower tonnages, existing data may be available for some  
6 substances. These are most frequently from acute studies, and this document provides  
7 guidance on their interpretation and use. Nevertheless, data from long-term dietary  
8 studies are the most relevant because:

- 9
- Few (if any) scenarios are likely to lead to acute poisoning risks for birds, and
  - Evidence from pesticides suggests that chronic effects cannot be reliably  
10 extrapolated or inferred from acute toxicity data (Sell, undated).
- 11

#### 12 **PBT/vPvB assessment:**

13 In the context of the PBT/vPvB assessment, if the registrant cannot derive a definitive  
14 conclusion (i) ("The substance does not fulfil the PBT and vPvB criteria") or (ii) ("The  
15 substance fulfils the PBT or vPvB criteria") in the PBT/vPvB assessment using the  
16 relevant available information, he must, based on Section 2.1 of Annex XIII to REACH,  
17 generate the necessary information, regardless of his tonnage band (for further details,  
18 see Chapter R.11 of the *Guidance on IR&CSA*).

19 The general presumption is that avian toxicity testing will not normally be necessary. At  
20 the same time, care must be taken not to underestimate the potential hazard to birds.  
21 New studies should only be proposed following careful consideration of all the available  
22 evidence.

#### 23 **R.7.10.18 Available information on avian toxicity**

24 The following sections summarise the types of data that may be available from  
25 laboratory tests.

26 Avian toxicity tests are often carried out for substances with intentional biological activity  
27 as a result of regulatory approval requirements (especially active substances used in  
28 plant protection products, but also veterinary medicines and biocides). They are rarely  
29 performed for most other substances. Although REACH does not apply to such products,  
30 they are relevant in this context as a source of analogue data.

31 There are currently no European databases for pesticides, biocides or veterinary  
32 medicines, although some are in development (e.g. the Statistical Evaluation of available  
33 Ecotoxicology data on plant protection products and their Metabolites (SEEM) database).  
34 Current pesticide data sources include:

- 35
- the British Crop Protection Council Pesticide Manual (BCPC, 2003),
  - 36 • the German Federal Biological Research Centre for Agriculture and Forestry  
37 (BBA) database (<http://www.bba.de/english/bbaeng.htm>),
  - 38 • the Institut National de la Recherche Agronomique (INRA) AGRITOX database  
39 ([www.inra.fr/agritox/php/fiches.php](http://www.inra.fr/agritox/php/fiches.php)),
  - 40 • the footprint database (<http://sitem.herts.ac.uk/aeru/iupac/>), and

- 1           • several US-EPA databases (<http://www.epa.gov/pesticides/>).

2 General searches might retrieve documents from regulatory agencies or the EXTTOXNET  
3 project (a co-operative project by the University of California-Davis, Oregon State  
4 University, Michigan State University, Cornell University, and the University of Idaho,  
5 <http://exttoxnet.orst.edu/>). Finally, IUCLID contains unvalidated data sheets for high  
6 production volume substances, a few of which might include data on avian toxicity  
7 (<http://esis.jrc.ec.europa.eu/>).

### 8 **R.7.10.18.1 Laboratory data on avian toxicity**

#### 9 **Testing data on avian toxicity**

##### 10 *In vitro* data

11 No specific avian *in vitro* methods are currently available or under development. A  
12 number of *in vitro* tests for assessing embryotoxic potential and endocrine disrupting  
13 properties in mammals have become available in recent years, and these are discussed  
14 in the specific guidance on reproductive and developmental toxicity (see Section R.7.6).

##### 15 *In vivo* data

16 [Table R.7.10–4](#) summarises the main existing test methods, as well as those proposed  
17 as draft OECD test guidelines. The guidelines for all three principal avian tests – acute,  
18 dietary and reproduction – are currently under review. Further details can be found in a  
19 Detailed Review Paper for Avian Two Generation Tests (OECD 2006a). It should be noted  
20 that acute tests will not be relevant to exposure scenarios normally considered for  
21 industrial and consumer chemicals, but they are included since the data might already  
22 be available for some substances.

23 A number of reviews of avian toxicity testing issues have been produced over the last  
24 decade, and these should be consulted if further details are required. All have a pesticide  
25 focus. The most up-to-date reviews are Hart *et al.* (2001), Mineau (2005), Bennett *et al.*  
26 (2005) and Bennett & Etterson (2006). Other useful sources of information include US-  
27 EPA (1982a, 1982b and 1982c), SETAC (1995), OECD (1996), EC (2002a and 2002b)  
28 and Eppo (2003).

29 Non-guideline toxicity studies may be encountered occasionally (e.g. egg exposure  
30 studies involving either injection or dipping). Such studies can be difficult to interpret  
31 due to the lack of standardised and calibrated response variables with which to compare  
32 the results. In addition, the exposure route will usually be of limited relevance to the  
33 dietary exposure route considered in the CSA. Metabolism in eggs may also be very  
34 different to that in the body. Such studies are therefore unlikely to provide information  
35 on use in quantitative risk assessment, although they might provide evidence of toxicity  
36 that requires further investigation.

#### 37 **Non-testing data on avian toxicity**

##### 38 (Q)SAR models

39 Toxicity to Bobwhite Quail following both 14-day oral and 8-day dietary exposure can be  
40 predicted for pesticides and their metabolites using a free web-based modelling tool  
41 called “DEMETRA” (Development of Environmental Modules for Evaluation of Toxicity of

1 pesticide Residues in Agriculture) (<http://www.demetra-tox.net/>; Benfenati, 2007). The  
2 model was developed using experimental data produced according to official guidelines,  
3 and validated using external test sets. A number of quality criteria have been addressed  
4 according to the OECD guidelines<sup>8</sup>. It is unclear at the moment whether this model will  
5 be useful for other types of substance.

6 No other Q(SAR) models are currently available.

7

---

<sup>8</sup> The ECB may wish to produce a QRF to provide details on domain, no. of chemicals in training set, etc.

1 **Table R.7.10—4 Summary of existing and proposed standardised avian**  
 2 **toxicity tests**

| Test                             | Guideline  | Summary of the test  | Information derived  |
|----------------------------------|--|--|--|
| Acute oral toxicity <sup>9</sup> | Draft OECD TG 223 (OECD, 2002)<br><br>USEPA/OPPTS 850.2100 (US-EPA, 1996a) | The test involves direct exposure of birds to measured single oral doses of the test substance, followed by observation for a number of days. Administration is by gavage either in a suitable solvent vehicle or in gelatine capsules. The highest dose need not exceed 2,000 mg/kg bw.<br><br>Regurgitation should be avoided because it compromises the evaluation of toxicity. Lowering dose volume or changing carriers may reduce the incidence of regurgitation.  | The test provides a quantitative measurement of mortality (LD <sub>50</sub> value), which acts as a standard index of inherent toxicity, since bird behaviour (i.e. dietary consumption) cannot influence the dose received. It is therefore useful as a general guide for range finding for other studies, and for comparative studies.<br><br>The results are relevant to very short timescale exposures, and cannot be used to indicate chronic toxicity. This test is therefore of low relevance for the assessment of food chain risks. |
| Dietary toxicity                 | OECD TG 205 (1984a)<br><br>USEPA/OPPTS 850.2200 (US-EPA, 1996b)            | This is a short-term test, in which groups of 10-day old birds are exposed to graduated concentrations (determined in a range-finding test) of the test substance in their diet for a period of 5 days, followed by a recovery period. Multiple oral dosing may be necessary for very volatile or unstable compounds.<br><br>The test is not designed to simulate realistic field conditions, or provide a good characterisation of sub-lethal effects. Other drawbacks include:<br><br>food avoidance <sup>10</sup> , and lack of replication (which limits the power of the test to detect effects). | The test provides a quantitative measurement of mortality (e.g. 5-day LC <sub>50</sub> value) and can act as a range-finder for the chronic reproduction test (a full test is not necessary if the range-finding test shows that the LC <sub>50</sub> is above 5,000 mg/kg diet).  |

<sup>9</sup> Efforts to combine these two test methods into one internationally harmonized test guideline are currently ongoing in the OECD Test Guideline Programme

<sup>10</sup> Food avoidance responses can influence a substance's hazard and also risk potential by restricting exposure, although this will vary between species. A draft OECD Guidance Document on Testing Avian Avoidance Behaviour is under development (OECD 2003). In the current revision of TG 205 the method will be revised to generate information that also can be used for the assessment of avoidance behaviour. There are no international protocols on avian repellency yet available. However a purpose of such a test i.e. the screening of repellent substances could be achieved by using the results of a revised dietary guideline (OECD, 2006b). Repellency is of limited

| Test                       | Guideline  | Summary of the test  | Information derived   |
|----------------------------|--|--|---|
| Reproduction <sup>11</sup> | OECD TG 206 (1984b)<br><br>USEPA/ OPPTS 850.2300 (US-EPA, 1996c) | <p>Breeding birds are exposed via the diet over a long-term (sub-chronic) period to at least three concentrations of the test substance. The highest concentration should be approximately one half of the acute dietary LC<sub>10</sub>; lower concentrations should be geometrically spaced at fractions of the highest dose. An upper dose limit should be set at 1,000 ppm (unless this would cause severe parental toxicity).</p> <p>The test substance should possess characteristics that allow uniform mixing in the diet. The test guideline cannot be used for highly volatile or unstable substances.</p> | <p>The test enables the identification of adverse effects on reproductive performance linked to gonadal functionality at exposure levels lower than those that cause serious parental toxicity.</p> <p>The most important endpoint is the production of chicks that have the potential to mature into sexually viable adults. Other intermediate parameters are also measured (e.g. mortality of adults, onset of lay, numbers of eggs produced, eggshell parameters, fertility, egg hatchability and effects on young birds). These can give information on the mechanisms of toxicity that contributes to overall breeding success.</p> <p>The test should provide a NOEC value (i.e. the concentration in adult diet that shows no reduction in the production of viable chicks) along with the statistical power of the test.</p> <p>It is critical that all endpoints be taken into account when using the results from the test for risk assessment. The weight given to intermediate endpoints in the absence of a problem in overall chick production is a case-by-case decision which must be made after consideration of the possible or likely consequences in the wild. The ecological significance of effects on each of the parameters measured may differ.</p> |

relevance for long-term endpoints involving only low concentrations of test substance. Further guidance, if needed, can be found in the references cited in the main text.

<sup>11</sup> Some work has been done to develop a one-gen test OECD draft TG (2000) Avian Reproduction Toxicity Test in the Japanese Quail or Northern Bobwhite) but this is not yet at a suitable stage to be discussed further.

| Test   | Guideline                                  | Summary of the test   | Information derived   |
|--|--|---|---|
| <p>OECD TG 206 was not designed to accurately reflect a bird's full breeding cycle, and some ecologically important endpoints are not covered (e.g. the onset of laying, parental competence in incubation, and feeding of young birds). Although these might not always be significant gaps, further work is underway to develop a test that will be able to detect all the potential effects of endocrine disrupting chemicals, and this is described briefly below.</p> |  |   |   |
| <p>Two-generation avian reproduction toxicity</p>  | <p>Draft OECD TG proposal (OECD, 2006)</p> | <p>The proposed guideline aims to examine the effects of a chemical on a broad set of reproductive fitness and physiological endpoints in a quail species over two generations. However, several research areas have been identified, and an agreed test guideline is unlikely to be available for some time.</p> | <p>The test is designed to determine whether effects are a primary disturbance (with direct impacts on the endocrine system) or a secondary disturbance (with impacts on other target organs that cause endocrine effects) of endocrine function. Currently, endpoints to be covered include egg production and viability, hatching success, survival of chicks to 14 days of age, genetic sex, onset of sexual maturation, body weight, and male copulatory behaviour, gross morphology and histology of specific organs, as well as levels of sex hormones, corticosterone, and thyroid hormones.</p> |

2

1 Read-across and categories

2 Experience of read-across approaches for avian toxicity is very limited for industrial and  
3 consumer chemicals. The same approach should therefore be adopted as for mammalian  
4 tests (see Section R.7.6 for specific guidance on reproductive and developmental  
5 toxicity).

6 In addition, it should be considered whether the chemical has any structural similarity to  
7 other substances to which birds are known to be especially sensitive, such as  
8 organophosphates, certain metals and their compounds (e.g. cadmium, lead, selenium)  
9 and certain pesticide or veterinary medicine active substances (e.g. DDT). Further  
10 research is needed to identify structural alerts for chronic avian toxicity.

11 **R.7.10.18.2 Field data on avian toxicity**

12 Field data will not usually be available, and it is unlikely that a registrant will ever need  
13 to conduct a specific field study to look for bird effects (as sometimes required for  
14 pesticides). Recommendations on methodology are given in EC (2002a) and further  
15 discussion is provided in Hart *et al.* (2001) and SETAC (2005). The kind of data that  
16 result from such studies varies according to the test design, although they tend to focus  
17 on short-term impacts and are therefore of limited use for risk assessment of long-term  
18 effects.

19 Wildlife incident investigation or other monitoring schemes might rarely provide some  
20 evidence that birds are being affected by exposure to a specific substance. Interpretation  
21 is often complicated and it may be difficult to attribute the observed effects to a specific  
22 cause. However, such data can be used to support the assessment of risks due to  
23 secondary poisoning on a case-by-case basis.

24 **R.7.10.19 Evaluation of available information on avian toxicity**

25 **R.7.10.19.1 Laboratory data on avian toxicity**

26 **Testing data on avian toxicity**

27 In vitro data

28 No specific avian methods are currently available. The specific guidance on reproductive  
29 and developmental toxicity (see Section R.7.6) provides guidance on evaluation of some  
30 types of test that are relevant to mammalian reproduction. It should be noted that these  
31 are only relevant for one – albeit very important – aspect of long-term toxicity. In  
32 addition, these tests do not take metabolism into account, and metabolic rates and  
33 pathways may differ significantly between birds and mammals.

34 In vivo data

35 Ideally, test results will be available from studies conducted to standard guidelines with  
36 appropriate quality assurance, reported in sufficient detail to include the raw data. Data  
37 from other studies should be considered on a case-by-case basis. For example, expert  
38 judgement is needed to identify any deviations from modern standards and assess their  
39 influence on the credibility of the outcome. A non-standard test might provide an  
40 indication of possible effects that are not identified in other studies or evidence of very  
41 low or high toxicity. If the data are used, this must be scientifically justified.

1 For tests involving dietary exposure, stability and homogeneity of the substance in the  
 2 food must be maintained. Results of studies involving highly volatile or unstable  
 3 substances therefore need careful consideration, and it might not be possible to  
 4 adequately test such substances or those that otherwise cannot be administered in a  
 5 suitable form in the diet. In such cases, it is unlikely that birds would be exposed to the  
 6 substance in the diet either, for similar reasons. If a vehicle is used, this must be of low  
 7 toxicity, and must not interfere with the toxicity of the test substance. Validity criteria  
 8 are given in the OECD guidelines.

#### 9 Acute/short-term tests

10 Existing acute test data can be useful if no other avian data are available, although they  
 11 are not preferred. Regurgitation/emesis can substantially reduce the dose absorbed in  
 12 acute oral toxicity tests, and therefore affect the interpretation of the test results.  
 13 Similarly, food avoidance in dietary tests may lead to effects related to starvation rather  
 14 than chemical toxicity. Tests should therefore be interpreted carefully for any evidence of  
 15 such responses - the test may not be valid if regurgitation occurs at all doses.

#### 16 Long-term tests

17 A number of issues should be considered in the evaluation of long-term tests, as listed in  
 18 [Table R.7.10–5](#). In principle, only endpoints related to survival rate, reproduction rate  
 19 and development of individuals are ecotoxicologically relevant.

### 20 **Table R.7.10–5 Summary of interpretational issues for long-term toxicity** 21 **tests**

| Long-term testing issue | Comment  |
|-------------------------|--|
| Category of endpoint    | <p>Reproduction tests include parental and reproductive endpoints. An endpoint relating to overall reproductive success should normally be selected to define the long-term NOEC. Depending on the individual case and the availability of data, this could be the reproduction rate, the survival or growth rate of the offspring, or behavioural parameters in adults or young.</p> <p>In some cases, other endpoints (e.g. certain biochemical responses) may be more sensitive, although they might not be ecologically relevant. Guidance on interpretation of such data, if they are available, is provided in OECD (1996). In summary, any conclusions of biological significance must be based on changes that:</p> <p>Occur in a dose-response fashion (i.e. more abundant or pronounced in higher exposure groups);</p> <p>Are accompanied by confirmatory changes (i.e. differences in a biochemical parameter or organ weight, or histologically observable changes in tissue structure); and,</p> <p>Most importantly, are related to an adverse condition that would compromise the ability of the animal to survive, grow or reproduce in the wild (e.g. pronounced effects on body weight and food consumption (if this is a toxic response and not caused by avoidance)).</p> |

| Long-term testing issue | Comment  |
|-------------------------|--|
| Statistical power       | <p>The NOEC is based on the most sensitive endpoint of the test as determined by the lack of statistical significance compared with the control. This does not necessarily equate to biological significance. For example, in a high quality (low variation coefficient, high power) avian reproduction test it may be possible to prove that a 5% deviation in hatchling weight is statistically significant, although this would not be detectable in normal tests. If the chick weight at day 14 is normal, such an effect should not be considered as biologically relevant.</p> <p>The NOEC may therefore be used as a worst case value for risk assessment, but it may be possible to refine this if necessary by considering the ecological relevance of the effects seen at doses above the NOEC (e.g. see Bennett <i>et al.</i>, 2005).</p> |
| Time course of effects  | <p>Sublethal effects that are transient or reversible after termination of exposure are less relevant than continuous or irreversible effects (this may depend on how fast the reversal takes place). If reproductive effects in a multigeneration study are more pronounced in the second generation whereas in practice exposure will be restricted to a short time period then the reproductive NOEC after the first generation should be used as a possible refinement step (unless in exceptional cases, e.g. with suspected endocrine disrupters, where effects in the second generation may be attributable to a brief exposure period in the first generation).</p>  |
| Parental toxicity       | <p>Parental toxicity should be avoided if possible. Effects that are only observed in the concentration range that leads to clear parental toxicity need careful consideration. For example, a decline in egg laying may be the result of reduced feeding by the adult birds, and would therefore not be a reproductive effect.</p>  |
| Exposure considerations | <p>For highly hydrophobic substances, or substances that are otherwise expected to be significantly accumulative, measurements of the substance in tissues should be considered as an additional endpoint to determine whether concentrations have reached a plateau before the end of the exposure period.</p>  |

1

2 **Non-test data on avian toxicity**

3 (Q)SAR models

4 If QSAR models that have been developed for pesticides are used, their relevance for a  
5 particular substance should be considered and explained (especially in relation to the  
6 applicability domain). It is likely that QSAR approaches will not be suitable for the  
7 majority of substances for the foreseeable future, in terms of both the endpoints covered  
8 (i.e. acute effects only) and the chemical domain.

9 Read-across and categories

10 The same principles apply as for mammalian acute toxicity (see Section R.7.4), repeated  
11 dose toxicity (Section R.7.5) and reproductive toxicity studies (Section R.7.6). Ideally,  
12 the substances should have similar physico-chemical properties and toxicokinetic  
13 profiles, and information will be available about which functional groups are implicated in  
14 any observed avian toxicity. The comparison should take account of reproductive or  
15 other chronic effects observed in fish and mammals as well as birds. The absolute

1 toxicity of a substance cannot be directly extrapolated from fish or mammals to birds,  
2 but relative sensitivities might provide enough evidence in some circumstances.

### 3 **R.7.10.19.2 Field data on avian toxicity**

4 It will be very unusual for field studies to indicate chronic effects in wild birds, and these  
5 need to be considered case-by-case. Results should be interpreted with caution, and  
6 confounding factors addressed before deciding what level of any particular substance is  
7 linked to the observed effect. The relevance and statistical power of the study should  
8 also be assessed. Further discussion is provided in Hart *et al.* (2001) and OECD (1996).

### 9 **R.7.10.19.3 Remaining uncertainty for avian toxicity**

10 Avian toxicity data are not available for the majority of substances. Assessments of  
11 secondary poisoning are therefore usually reliant on mammalian toxicity data. The  
12 relative sensitivities of birds and mammals following chronic exposures require further  
13 research. For example, there is some evidence from pesticide data that birds may be an  
14 order of magnitude more sensitive in some cases. The validity of read-across between  
15 analogue substances is also untested.

16 Even when studies are available, there are still many sources of uncertainty that need to  
17 be taken into account in the assessment of avian effects. Only a very few species are  
18 tested in the laboratory, and it is important to be aware that there is significant variation  
19 in response between species and individuals, and differences between laboratory and  
20 field situations (e.g. diet quality, stressors, differing exposures over time). Further  
21 details are provided in Hart *et al.* (2001). These issues are assumed by convention to be  
22 accounted for collectively using an extrapolation or assessment factor (see Section  
23 [R.7.10.20](#)). It should be noted that these factors have not been calibrated against the  
24 uncertainties.

25 In addition, it should be remembered that the model food chain for the screening  
26 assessment of secondary poisoning risks is relatively simplistic and reliant on a number  
27 of assumptions (see Section [R.7.10.8](#) for further details). It may often be possible to  
28 refine the exposure scenario (e.g. by more sophisticated modelling, including use of  
29 more specific information about the most significant prey and predator organisms of the  
30 food chain considered concerning for example bioavailability of the substance in food  
31 and feeding habits and/or gathering better exposure information such as emission,  
32 degradation or monitoring data). Regardless of the calculations that are performed, it is  
33 always useful to perform a sensitivity analysis, i.e. list those items that have some  
34 associated uncertainty, and discuss whether these uncertainties can be quantified  
35 together with their overall impact on the conclusions of the assessment.

36 For complex mixtures, the toxicity test result is likely to be expressed in terms of the  
37 whole substance. However, the exposure concentration may be derived for different  
38 representative components, in which case the PEC/PNEC comparison will require expert  
39 judgement to decide if the toxicity data are appropriate for all components, and whether  
40 further toxicity data are needed for any specific component.

### 41 **R.7.10.19.4 Exposure considerations for avian toxicity**

42 No specific exposure-related exclusion criteria are provided in column 2 of Annex X.

1 In pesticide risk assessment, decisions on the need for reproduction tests may depend  
2 on whether adult birds are exposed during the breeding season (EC, 2002a). However, it  
3 is highly unlikely that the use of an industrial or consumer chemical would be so  
4 restricted as to exclude breeding season exposure. In some cases, the use pattern might  
5 limit exposure to birds. For example, production and use might only take place at a small  
6 number of industrial sites with very low releases, with low probability of any significant  
7 release from products (an example might be a sealant additive). In cases where the  
8 exposure is considered negligible, an appropriate justification should be given, taking  
9 care that this covers all stages of the substance's life cycle.

10 If releases to air, water and/or soil can occur, then the need to perform a new avian  
11 toxicity test at the 1,000 t/y level should be decided following a risk assessment for  
12 secondary poisoning. It should be noted that the exposure of birds is generally only  
13 considered for the fish and earthworm food chains following the release of a substance  
14 via a sewage treatment works<sup>12</sup>. The need to conduct a secondary poisoning assessment  
15 is triggered by a number of factors (see Section R.16.4.3.5 for further guidance). If  
16 these criteria are not met, then further investigation of chronic avian toxicity is  
17 unnecessary. For example, it is unlikely that a secondary poisoning risk will be identified  
18 for substances that:

- 19 • are readily biodegradable, and
- 20 • have a low potential for bioaccumulation in fish and earthworms (e.g. a fish  
21 BCF below 100, or in the absence of such data on neutral organic substances  
22 a log K<sub>ow</sub> below 3).

23 These properties may therefore be used as part of an argument for demonstrating low  
24 exposure potential for birds, although care may be needed (e.g. high local  
25 concentrations could still be reached in some circumstances, for example due to  
26 widespread continuous releases).

#### 27 **R.7.10.20 Conclusions for avian toxicity**

28 The aim is to derive a PNEC for birds based on the available data. Given the absence of  
29 reliable QSARs and *in vitro* methods, in most cases it is expected that an initial attempt  
30 to estimate avian toxicity can be made by read-across from suitable analogue  
31 substances (possibly as part of a category). The preferred value must be scientifically  
32 justified for use in the assessment.

##### 33 **R.7.10.20.1 Concluding on suitability for PBT/vPvB assessment**

34 In the context of PBT/vPvB assessment, avian toxicity data should be used in conjunction  
35 with other evidence of toxicity as part of a weight-of-evidence determination to conclude  
36 on substance toxicity. If the existing avian toxicity study is of poor quality, or the effect  
37 is unclear or based on only minor symptoms, an additional study might be needed if the  
38 decision is critical to the overall assessment, in which case a limit test would be  
39 preferred. The ecological significance of the effect should also be considered (e.g. how

---

<sup>12</sup> It may sometimes be appropriate to model exposure of marine predators, in which case the scenario might not involve a sewage treatment stage.

1 important is a sub-lethal effect compared to those of natural stressors, and what would  
2 be their effect on population stability or ecosystem function?). Further guidance is  
3 provided in Bennett *et al.* (2005).

4 Further guidance on criteria is provided in Chapter R.11 of the *Guidance on IR&CSA*.

#### 5 **R.7.10.20.2 Concluding on suitability for use in chemical safety** 6 **assessment**

7 Data obtained from species used in standard test methods are assumed to be  
8 representative of all species (including marine). Since the scenario under consideration  
9 concerns the effects of a chemical on birds via their diet, only toxicity studies using oral  
10 exposure are relevant. Dietary studies are preferred, since these are most relevant to  
11 the exposure route under investigation. Oral gavage studies might provide some  
12 evidence of very high or low acute toxicity in some cases, which could be used as part of  
13 a *Weight-of-Evidence* argument provided that a reasoned case is made. Egg dipping  
14 studies are not relevant, although they might indicate an effect that requires further  
15 investigation.

#### 16 **R.7.10.21 Integrated testing strategy (ITS) for avian toxicity**

##### 17 **R.7.10.21.1 Objective / General principles**

18 In general, a test strategy is only relevant for substances made or supplied at levels of  
19 1,000 t/y or higher (although there may be a need for further investigation if a risk is  
20 identified at lower tonnage based on existing acute data). Furthermore, collection and/or  
21 generation of additional avian toxicity data are required for the PBT/vPvB assessment in  
22 all cases where a registrant, while carrying out the CSA, has identified is substance as P  
23 and B but cannot draw an unequivocal conclusion on whether the T criterion in Annex  
24 XIII to REACH is met or not and avian toxicity testing would be needed to draw a  
25 definitive conclusion on T. This obligation applies for all  $\geq 10$  tpa registrations (see  
26 Chapter R.11 of the *Guidance on IR&CSA* for further details).

27 The general presumption is that avian toxicity testing will not normally be necessary. At  
28 the same time, care must be taken not to underestimate the potential risks faced by  
29 birds. New studies should only be proposed following careful consideration of all the  
30 available evidence, and the objective of the testing strategy is therefore to ensure that  
31 only *relevant* information is gathered.

##### 32 **R.7.10.21.2 Preliminary considerations**

33 The need for chronic avian toxicity testing is explicitly linked to the secondary poisoning  
34 assessment. A decision on the need to conduct avian testing may be postponed if other  
35 actions are likely to result from the rest of the environmental (or human health)  
36 assessment. For example:

- 37 • No further testing on birds is necessary if the substance is a potential PBT or  
38 vPvB substance on the basis of other data (the relevant PBT test strategy  
39 should be followed first). If such properties were confirmed, then further  
40 animal testing would be unnecessary since long-term effects can be  
41 anticipated.

- 1           • The exposure assessment may need to be refined if risks are initially identified  
2 for the aquatic or terrestrial environments. This may include the  
3 recommendation of improved risk management measures.
- 4           • A test with birds can await the outcome of any further chronic mammalian  
5 testing proposed for the human health assessment (unless it is already  
6 suspected that birds may be more sensitive, e.g. because of evidence from  
7 analogue substances).

8 Three main cases can be distinguished where further testing may be an option:

- 9           • **Only acute avian toxicity data are available.** A decision on the need for  
10 further chronic testing will depend on the outcome of the risk assessment  
11 using a PNEC based on these data, in comparison to the conclusions for  
12 mammalian predators. For example, if a risk is identified for birds but not  
13 mammals, a chronic test will allow the PNEC<sub>bird</sub> to be refined.
- 14           • **Only a poor quality chronic study is available.** If the risk is borderline  
15 (e.g. the PEC is only just greater or less than the resulting PNEC), a  
16 replacement study might be necessary to provide more confidence in the  
17 conclusion.
- 18           • **No avian toxicity data are available.** A decision must be made as to  
19 whether this represents a significant data gap or not. It is assumed that a risk  
20 characterisation based on the available mammalian toxicity data set will give  
21 an indication of the possible risks of the chemical to higher organisms in the  
22 environment (care should be taken to consider any effects that have been  
23 excluded as irrelevant for human health). However, given the lack of  
24 information on relative sensitivities between birds and mammals, avian  
25 testing may be required if:
- 26                 - the substance has a potential for contaminating food chains – for  
27 example, because it is not readily biodegradable and is accumulative  
28 (e.g. fish BCF above 100, or other indications of bioaccumulation from  
29 mammalian tests such as low metabolic rate, high affinity for fat  
30 tissues, long period to reach a plateau concentration in tissues, or slow  
31 elimination rate), and
- 32                 - there is evidence of toxicity in mammalian repeat dose or reproduction  
33 tests.
- 34                     As a toxicity testing trigger *only*, it is suggested that the PNEC<sub>mammal</sub> is  
35 reduced by a factor of 10 to derive a *screening* PNEC<sub>bird</sub>: if the  
36 subsequent risk characterisation ratio is above 1, and the exposure  
37 assessment cannot be refined further, then avian toxicity data should  
38 be sought (see Section [R.7.10.21.3](#)).

39 In all cases before a new toxicity test is performed, efforts should first be made to refine  
40 the PEC (including consideration of risk management measures) because the exposure  
41 scenario is based on a number of conservative assumptions. If avian testing is  
42 necessary, a limit test might be appropriate.

43

### 1 **R.7.10.21.3 Testing strategy for avian toxicity**

2 This assumes that chronic avian toxicity needs to be addressed. If no suitable analogue  
3 data exist (which will often be the case), or there is some doubt about the validity of the  
4 read-across, further testing is required on the substance itself. This may also be the case  
5 if the substance is part of a larger category for which avian toxicity data are limited (in  
6 which case it might be possible to develop a strategy to provide data on several related  
7 substances, based on a single (or few) test(s). The substance that appears the most  
8 toxic to mammals and fish should be selected for further testing with birds in the first  
9 instance).

10 The avian reproduction test (OECD TG 206) should be conducted to provide a reliable  
11 chronic NOEC. It may be possible to conduct a limit test (based on the highest PEC  
12 multiplied by 30): if no effects are observed at this limit concentration then no further  
13 investigation is necessary. A judgment will be needed as to whether this approach is  
14 likely to offer any disadvantage compared to a full test (e.g. the substance may be part  
15 of a category, where further information on dose-response may be needed). Exceptions  
16 to this test may be as follows:

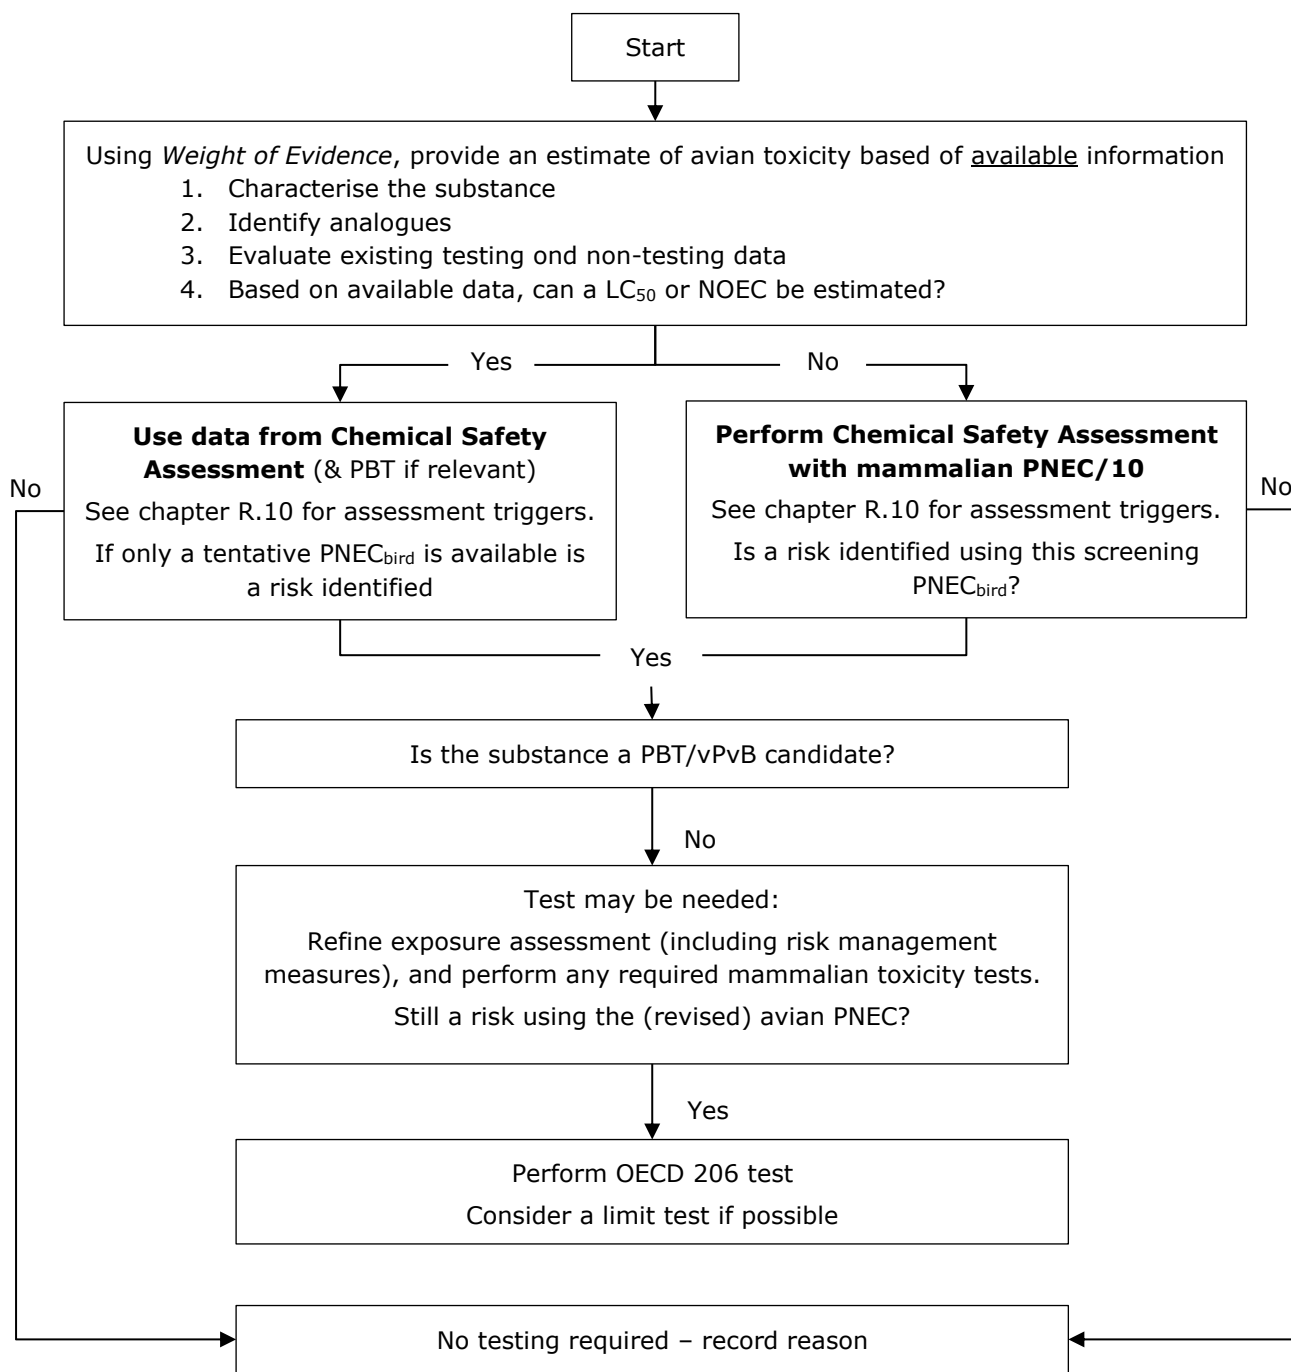

- 17 • In some cases, it might be appropriate to conduct an acute test to provide a  
18 preliminary indication of avian toxicity. For example, this could be useful if  
19 several related substances have no avian toxicity data, and some comparative  
20 data are needed to test the appropriateness of a read-across argument when  
21 only one is subject to a reproduction test. This could be a limit test in the first  
22 instance, since it is not necessary to establish a full dose-response  
23 relationship. A tentative  $PNEC_{oral}$  can be derived from the result of a dietary  
24 test (OECD TG 205), in which case the limit could be either 5,000 mg/kg diet  
25 or the highest PEC multiplied by 3,000 (whichever is the lowest). However,  
26 given the uncertainties in extrapolating from acute to chronic effects, a  
27 chronic test will usually be preferred.
- 28 • If the substance clearly shows an endocrine disrupting effect in mammals with  
29 a high potency (i.e. acting at doses well below the threshold for other  
30 endpoints), it may be appropriate to conduct a multi-generation test instead.  
31 Since the protocols for such tests have not been internationally agreed, these  
32 would need to be discussed with the relevant regulatory bodies before  
33 embarking on a study. In addition, it is likely that such substances would be  
34 authorised and so the sacrifice or more vertebrates might not be justified.

35 It should be noted that this scheme does not include requirements to collect field data.  
36 This should only be considered in exceptional circumstances.

37 The ITS is presented as a flow chart in [Figure R.7.10–2](#).

## Appendices to Section R.7.10

- [Appendix R.7.10-1](#) Databases
- [Appendix R.7.10-2](#) *In vitro* methods for aquatic bioaccumulation
- [Appendix R.7.10-3](#) Considerations for difficult substances
- [Appendix R.7.10-4](#) Quality criteria for data reliability of a (flow-through) fish bioaccumulation study

1 **Appendix R.7.10-1 Databases**

2

3 Several BCF databases are available and the most widely used are described in this  
4 appendix (see Weisbrod *et al.* (2006) for additional details). Many of the earlier studies  
5 recorded in databases suffer from a number of potentially serious flaws, which are  
6 gradually being better understood. For example, the methodology may not always be  
7 consistent with the current OECD 305 test guideline. It is therefore important that the  
8 version of the database being interrogated is recorded, because the content may change  
9 over time. For example, following a quality control of the Syracuse database, a number  
10 of values were amended or removed. In a number of cases, the data quality might not  
11 have been checked, and in these circumstances the original source should also be sought  
12 so that the quality can be confirmed.

13 **AQUIRE / ECOTOX Database**

14 A very well known and widely used database is the AQUatic toxicity Information  
15 REtrieval (AQUIRE) (US-EPA, 1995) system, which is a part of the United States  
16 Environmental Protection Agency's ECOTOX Database (US-EPA ECOTOX Database). In  
17 2005 more than 480,000 test records, covering 6,000 aquatic and terrestrial species and  
18 10,000 chemicals, were included. The primary source of ECOTOX data is the peer-  
19 reviewed literature, with test results identified through comprehensive searches of the  
20 open literature. The bioconcentration factor sub-file includes 13,356 aquatic chemical  
21 records and 19 terrestrial chemical records, collected from over 1,100 publications, and  
22 encompassing approximately 700 distinct chemicals. The use of the on-line database is  
23 free and can be accessed through the Internet at <http://cfpub.epa.gov/ecotox/>.

24 **Japan METI – NITE Database**

25 The METI database is a collection of around 800 BCF values collected by the Japanese  
26 National Institute of Technology and Evaluation (NITE). The database collects  
27 bioconcentration values obtained according to the OECD TG 305C method (older data) as  
28 well as the more recent version of the OECD TG. The test fish (carp) is exposed to two  
29 concentrations of the test chemical substance in water under flow-through conditions. All  
30 tests are conducted by Good Laboratory Practice (GLP) laboratories and their test results  
31 are reviewed by the joint council of 3 ministries (METI: Ministry of Economy, Trade and  
32 Industry; MHLW: Ministry of Health, Labour and Welfare; MoE: Ministry of the  
33 Environment). The BCF data on about 800 existing chemicals are available at the  
34 Chemical Risk Information Platform (CHRIP) of the NITE's web site  
35 (<http://www.nite.go.jp/en/chem/index.html>). Maximum and minimum BCFs at two  
36 different exposure concentrations for the test species (*Carp, Cyprinus carpio*) are  
37 reported. The duration of exposure and exposure method (usually flow through) and lipid  
38 content are usually provided and occasionally the analytical method (e.g. gas  
39 chromatography) is included. However, it has to be highlighted that earlier studies were  
40 not conducted in accordance with the current OECD TG 305 method. Some used high  
41 levels of solvents/dispersants (which may give unreliable BCF values) and others were  
42 conducted far in excess of the test substance's water solubility limit (which may produce  
43 an underestimate of the BCF value).

44

## 1 US National Library of Medicine's Hazardous Substances Database

2 The Hazardous Substances Database (HSDB) is a toxicology database on the National  
3 Library of Medicine's (NLM) Toxicology Data Network (TOXNET®). HSDB focuses on the  
4 toxicology of potentially hazardous chemicals. It includes over 4800 chemical records. All  
5 data are referenced and peer-reviewed by a Scientific Review Panel composed of expert  
6 toxicologists and other scientists (U.S. NLM 1999). Although the data are primary source  
7 referenced there is little information about the details of the experiments used o  
8 measure BCF. The Hazardous Substances Database is accessible, free of charge, via  
9 TOXNET at: <http://toxnet.nlm.nih.gov>.

## 10 Environmental Fate Database

11 The Environmental Fate Database (EFDB) database (Howard *et al.*, 1982, Howard *et al.*,  
12 1986) was developed by the Syracuse Research Corporation (SRC) under the  
13 sponsorship of the US-EPA. This computerized database includes several interconnected  
14 files, DATALOG, CHEMFATE, BIOLOG, and BIODEG. DATALOG is the largest file and it  
15 contains over 325,000 records on over 16,000 chemicals derived from the literature. The  
16 bioaccumulation and bioconcentration information is available only for a small fraction of  
17 the chemicals in the database. The database does not differentiate between BCF values  
18 that are derived experimentally based on testing the substance in question in a  
19 bioconcentration test or mathematically without such testing. A large number of reported  
20 BCF data is based on calculated values. The database can be accessed via the Internet at  
21 <http://www.srcinc.com/what-we-do/efdb.aspx> and is free of charge.

## 22 Syracuse BCFWIN Database and BCFBAF Database

23 The Syracuse BCFWIN database was developed by Meylan and co-workers to support the  
24 BCFWIN program (Syracuse Research Corporation, Bioconcentration Factor Program  
25 BCFWIN). The database development is described in Meylan *et al.* (1999). Experimental  
26 details captured in the database included fish species, exposure concentration of test  
27 compound, percent lipid of the test organism, test method (equilibrium exposure *versus*  
28 kinetic method), test duration if equilibrium method, and tissue analysed for test  
29 compound (whole body, muscle fillet, or edible tissue). Data obtained by the kinetic  
30 method were preferred to data from the equilibrium method, especially for compounds  
31 with high log  $K_{ow}$  values, which are less likely to have reached equilibrium in standard  
32 tests. Where BCF data were derived from the equilibrium method, and steady state may  
33 not have been reached, especially for chemicals with high log  $K_{ow}$  values, the data  
34 chosen was in the middle of the range of values with the longest exposure times. Low  
35 exposure concentrations of test compound were favoured in order to minimize the  
36 potential for toxic effects and maximize the likelihood that the total concentration of the  
37 substance in water was equivalent to the bioavailable fraction. Warm-water fish were  
38 preferred to cold-water fish because more data were available for warm-water species.  
39 Fish species were preferred in the order fathead minnow > goldfish > sunfish > carp >  
40 marine species (this list is not all inclusive). Fathead minnow data were generally  
41 selected over data from other species because such data were available for a large  
42 number of chemicals, and because they have been used to develop log  $K_{ow}$ -based BCF  
43 estimation methods. The database contains 694 discrete compounds. BCFWIN database  
44 was updated (Stewart *et al.*, 2005) to improve prediction for hydrocarbons. The current  
45 BCFWIN hydrocarbons database contains BCF data on 83 hydrocarbons.

1 The BCFWIN™ model has now been updated and replaced by the BCFBAF™ model. The  
2 model is available from the US EPA website [https://www.epa.gov/tsca-screening-](https://www.epa.gov/tsca-screening-tools/epi-suitetm-estimation-program-interface)  
3 [tools/epi-suitetm-estimation-program-interface](https://www.epa.gov/tsca-screening-tools/epi-suitetm-estimation-program-interface)

4 BCFBAF™ estimates fish bioconcentration factors and its logarithm using two different  
5 methods. The first is the traditional regression based on log KOW plus any applicable  
6 correction factors, and is analogous to the WSKOWWIN™ method. The second is the  
7 Arnot-Gobas method, which calculates BCF from mechanistic first principles. BCFBAF also  
8 incorporates prediction of apparent metabolism half-life in fish, and estimates BCF and  
9 BAF for three trophic levels (Arnot and Gobas, 2003).

## 10 **Handbook of Physico-chemical Properties & Environmental Fate**

11 The Handbook of Physico-chemical Properties & Environmental Fate (Mackay *et al.*,  
12 2000), published by CRC, consists of several volumes, each covering a set of related  
13 organic chemical substances. It is available in book form and in a CD ROM format. The  
14 database provided in the book includes data on bioconcentration factors, octanol-water  
15 partition coefficient and several other physical chemical properties relevant for  
16 environmental fate assessments. Details about the BCF data have not been retrieved.

## 17 **Canadian database**

18 Environment Canada has developed an empirical database of bioconcentration factor  
19 (BCF) and bioaccumulation factor (BAF) values to assess the bioaccumulation potential  
20 of approximately 11,700 organic chemicals included on Canada's Domestic Substances  
21 List (DSL) as promulgated by The Canadian Environmental Protection Act 1999  
22 (Government of Canada, 1999). These data were collected for non-mammalian aquatic  
23 organisms, i.e. algae, invertebrates and fish, from approximately October 1999 until  
24 October 2005. The BCF data were compiled from a Canadian in-house database, the  
25 peer-reviewed literature and the above mentioned databases. Dietary feeding studies  
26 were not included in the data compilation. Values were compiled only if the test chemical  
27 and test organism could clearly be identified. BCF data were evaluated for quality  
28 according to a developed set of criteria based on standard test protocols (e.g. OECD TG  
29 305E). The database includes approximately 5,200 BCF and 1,300 BAF values for  
30 approximately 800 and 110 chemicals, respectively. A data confidence evaluation is  
31 included based on the data quality criteria and methods. The database is available on  
32 request through the Environment Canada-Existing Substances branch.

## 33 **CEFIC – LRI bio-concentration factor (BCF) Gold Standard Database**

34 A research project has been funded by the CEFIC-LRI ([www.cefic-lri.org/](http://www.cefic-lri.org/)) to establish a  
35 BCF Gold Standard Database. The development of a database holding peer reviewed  
36 high quality BCF is considered a valuable resource for future development of alternative  
37 tests. In addition, having such a database – into which new data points could also be  
38 added – would considerably ease the potential to develop and begin the process for  
39 validation of alternative BCF studies. For example the database could act as a validation  
40 set of chemicals, for alternatives. The project will develop quality criteria, gather fish  
41 bioconcentration data, and critically review them. To prevent duplication of work, close  
42 contacts are held with other related projects, the HESI-ILSI bioaccumulation group, the  
43 SETAC advisory group and other interested parties.

1 **Appendix R.7.10-2 In vitro methods for aquatic bioaccumulation**  
 2

3 [Table R.7.10–6](#) lists standardised *in vitro* methods for use of fish liver S9 fractions and  
 4 primary cryopreserved hepatocytes (and applicable extrapolation models), as well as  
 5 recent publications that evaluated these methods and used them to predict  
 6 biotransformation impacts on bioaccumulation.

7 [Table R.7.10–7](#) lists a summary of other *in vitro* test systems used to study chemical  
 8 biotransformation in fish.

9 Further details on the use of these methods are provided in Section [R.7.10.3.1](#).

10

1 **Appendix R.7.10-3 Considerations for difficult substances**

2

3 The estimation methods presented in Section [R.7.10.3.2](#) were generally derived for non-  
4 ionised organic substances. They are therefore of limited usefulness for a large number  
5 of other substances, including complex mixtures and chemicals that are charged at  
6 environmental pH (such as inorganic compounds). These may be collectively termed  
7 *difficult substances*, and this appendix provides guidance on their assessment.

8 **Inorganic substances**

9 The availability of inorganic substances for uptake may vary depending on factors such  
10 as pH, hardness, temperature and redox conditions, all of which may affect speciation.  
11 BCF values will therefore be influenced by water chemistry. In general, only dissolved  
12 ions are potentially available for direct uptake.

13 Whilst some organo-metallic substances (e.g. methyl-mercury) behave like non-polar  
14 organics and are taken up across cell membranes by passive diffusion, the uptake of  
15 many types of dissolved inorganic ions (particularly metals) largely depend on the  
16 presence of specific active transport systems (e.g. copper ATPases regulate the uptake  
17 and excretion of copper in cells, and occur in a wide range of species from bacteria to  
18 humans (Peña *et al.*, 1999; Rae *et al.*, 1999)). These systems are regulated by saturable  
19 kinetics, and the degree of uptake of a particular ion will also be strongly influenced by  
20 ligand binding and competitive interactions at the receptor site (e.g. Campbell, 1995;  
21 Mason and Jenkins, 1995). Once in the organism, the internal ion concentration may be  
22 maintained through a combination of active regulation and storage, which generally  
23 involves proteins or specific tissues rather than lipid (Adams, *et al.*, 2000; McGeer, *et*  
24 *al.*, 2003). Such homeostatic mechanisms allow the maintenance of total body levels of  
25 substances such as essential metals within certain limits over a range of varying external  
26 concentrations.

27 As a result of these processes, organisms may actively accumulate some inorganic  
28 substances to meet their metabolic requirements if environmental concentrations are low  
29 (leading to a high BCF). At higher concentrations, organisms with active regulation  
30 mechanisms may even limit their intake and increase elimination and/or storage of  
31 excess substance (leading to lower BCFs). There may therefore be an inverse  
32 relationship within a certain exposure concentration interval between exposure  
33 concentration and BCF value (McGeer, *et al.*, 2003). Active body burden regulation has  
34 been shown to occur in many aquatic species. Other species will, however, tend to  
35 accumulate metals and store these in detoxified forms (e.g. calcium or phosphate based  
36 granules, methallothionein-like protein binding, etc.), thereby homeostatically regulating  
37 the toxic body burdens (Rainbow, 2002; Giguère *et al.*, 2003). It must be recognized<sup>14</sup>  
38 however that in some cases the homeostatic regulation capacity may be exceeded at a  
39 given external concentration beyond which the substance will accumulate and become

---

<sup>14</sup> For some metals evidence indicates variation in BCF of around one order of magnitude when the water concentration varies over three orders of magnitude. The highest BCF values occur at the lowest exposure concentrations and generally BCF values at environmentally realistic concentrations should be used.

1 toxic. The relationship between accumulation and toxic effects for inorganic substances  
2 is complex, but is determined by the relative balance between the rates of uptake and  
3 depuration/detoxification (Rainbow, 2002).

4 The observed variability in bioaccumulation and bioconcentration data due to speciation  
5 and especially homeostatic regulation can therefore complicate the evaluation of data  
6 (Adams & Chapman, 2006). The data may be used for assessments of secondary  
7 poisoning and human dietary exposure. However, special guidance is required for  
8 classification of metals and inorganic substances are currently outside the scope of PBT  
9 assessments.

10 The octanol-water partition coefficient ( $K_{ow}$ ) is not a useful predictive tool to assess the  
11 bioaccumulation potential for inorganic substances. Some indication may be given by  
12 read-across of bioaccumulation and toxicokinetic information from similar elements or  
13 chemical species of the same element. Factors such as ionic size, metabolism, oxidation  
14 state, etc., should be taken into account if sufficient data exist. This may limit the  
15 potential for read-across between different chemical species.

16 The OECD TG 305 is generally appropriate for determining a fish BCF, provided that the  
17 exposures are carried out under relevant environmental conditions and concentrations.  
18 Experimental bioaccumulation data should be assessed carefully on a case-by-case  
19 basis, paying particular attention to the dissolved exposure concentration. Based on the  
20 assessment of available data using expert judgement, there are two possibilities:

- 21 • A case may be made that the substance is unlikely to pose a risk to predatory  
22 organisms or humans exposed via the environment either:
  - 23 - based on the absence of food web biomagnification and information  
24 showing that organisms in higher trophic levels are not more sensitive  
25 than those in lower trophic levels after long-term exposure, or
  - 26 - because it is an essential element and internal concentrations will be  
27 well-regulated at the exposure concentrations anticipated.

28 Any such claims should be made on a case-by-case basis and substantiated with  
29 evidence (e.g. from field studies). It should be remembered that while a substance may  
30 be essential for a particular organism, it might not be essential for others.

- 31 • In the absence of the information mentioned above, bioconcentration factors  
32 for fish and other aquatic organisms are derived from the available data and  
33 taken into account in the CSA in the usual way. In the absence of suitable  
34 data, new studies must be performed. Considering the issues discussed  
35 above, an approach that allows the straightforward interpretation of BCF/BAF  
36 values has not been developed yet. Biomagnification factors may be more  
37 useful, although care must be taken in assessing trophic transfer potential.  
38 For example, the bioavailability of an inorganic substance to a bird or  
39 mammal may vary from that in aquatic species because of differences in  
40 detoxification mechanisms and digestive physiology, and this should be taken  
41 into account. Information may be obtained from field studies, although data  
42 may also be obtained from aquatic or terrestrial laboratory food chain transfer  
43 experiments.

1

## 2 **Complex mixtures (including petroleum substances)**

3 Complex mixtures pose a special challenge to bioaccumulation assessment, because of  
4 the range of individual substances that may be present, and the variation in their  
5 physico-chemical and toxicological properties. It is generally not recommended to  
6 estimate an average or weighted BCF value because:

- 7 • the composition of the constituents in the aqueous phase may vary in a non-  
8 linear fashion with substance loading rate, so that the BCF will also vary as a  
9 function of loading;
- 10 • differences in analytical methods used to quantify the total substance may  
11 introduce significant uncertainties in interpreting results; and
- 12 • this approach fails to identify specific constituents that could exhibit a much  
13 higher bioconcentration potential than the overall mixture.

14 In principle, therefore, it is preferable to identify one or more constituents for further  
15 consideration that can be considered representative of other constituents in the mixture  
16 in terms of bioaccumulation potential (acting as a worst case in terms of read-across  
17 between the constituents – see Section [R.7.10.3.2](#) in the main text for further guidance).  
18 This could include the establishment of *blocks* of related constituents (e.g. for  
19 hydrocarbon mixtures). The BCF would be established for each selected constituent in  
20 the usual way (whether by prediction or measurement), and these data can then be  
21 used to evaluate the likely range of BCF values for the constituents of a given mixture.  
22 The OECD TG 305 method should be used if possible (i.e. provided that the constituents  
23 can be monitored for separately). If a further confirmatory step is needed, the most  
24 highly bioaccumulative constituent(s) should be selected for bioaccumulation testing  
25 (assuming this can be extracted or synthesised).

26 It should be noted that branching or alkyl substitution sometimes enhances  
27 bioconcentration potential (e.g. due to a reduction in the biotransformation rate and/or  
28 an increase in the uptake clearance). Care should be taken to consider such factors  
29 when choosing a representative constituent. A form of *sensitivity analysis* may be useful  
30 in confirming the selection of constituents to represent a particular complex mixture. The  
31 logic/relevance behind selection of certain constituents for further testing may also  
32 depend on regulatory needs (e.g. for hazard classification the particular % cut off values  
33 for classification).

34 If it is not possible to identify representative constituents, then only a broad indication of  
35 bioaccumulation potential can be obtained. For example, it might be possible to derive a  
36 range of  $K_{ow}$  values from a HPLC method, or a biomimetic approach could be used  
37 (based on measurement of total organic carbon). If a potential concern is triggered for  
38 bioaccumulation potential, expert advice will be needed to refine the results.

## 39 **Ionisable substances**

40 In general, ionised organic substances do not readily diffuse across respiratory surfaces,  
41 although other processes may play a role in uptake (e.g. complex permeation, carrier-  
42 mediated processes, ion channels, or ATPases). Dissociated and neutral chemical species

1 can therefore have markedly different bioavailabilities. It is therefore essential to know  
2 or estimate the pKa to evaluate the degree of ionization in surface waters and under  
3 physiological conditions (pH 3-9) (see Section R.7.1. for further details of the pKa and  
4 how to predict log  $K_{ow}$  at different pH).

5 Fish BCFs of ionised substances can be estimated using appropriate QSARs (e.g. Meylan  
6 *et al.*, 1999). In addition, the log BCF of an ionized substance may be estimated at any  
7 pH by applying a correction factor to the log BCF of the unionized form, based on the  
8 relationship between BCF and  $K_{ow}$ . This factor would be derived from the Henderson-  
9 Hasselbach equation as  $\log(10^{pH-pK_a}+1)$ . However, this may lead to underestimates of the  
10 BCF in some circumstances, since the ionised form may be more accumulative than  
11 suggested by its  $K_{ow}$  alone. For example, a correction factor of  $\log(4^{pH-pK_a}+1)$  was found  
12 to be more appropriate for a group of phenolic compounds by Saarikoski and Viluksela  
13 (1982). Escher *et al.* (2002) also showed that the  $K_{ow}$  is not always a good indicator of  
14 biological membrane-water partitioning for ionised organic chemicals when there is  
15 reactivity with cell constituents.

16 It is therefore apparent that assumptions about the bioaccumulation behaviour of ionised  
17 substances may lead to underestimates of the BCF. Where this is likely to be a  
18 significant factor in an assessment, a bioconcentration test with fish may be needed.  
19 This should preferably be carried out at an ecologically relevant pH at which the  
20 substance is at its most hydrophobic (i.e. non-ionised form, as either the free acid or  
21 free base) using an appropriate buffer (e.g. for an acid this would be at a pH below its  
22 pKa; for a base, this would be at a pH above its pKa).

23 Where a quantitative estimate of the BCF of the ionised form is not possible, the role of  
24 pH should at least be discussed qualitatively in the assessment.

### 25 **Surface active substances (surfactants)**

26 A chemical is *surface active* when it is enriched at the interface of a solution with  
27 adjacent phases (e.g. air). In general, surfactants consist of an apolar and a polar  
28 moiety, which are commonly referred to as the hydrophobic tail and the hydrophilic  
29 headgroup, respectively. According to the charge of the headgroup, surfactants can be  
30 categorised as anionic, cationic, non-ionic or amphoteric (Tolls & Sijm, 2000). This  
31 structural diversity means that bioaccumulation potential should be considered in  
32 relation to these subcategories rather than the group as a whole (see Tolls *et al.* (1994)  
33 for a critical review).

34 Surfactants may form micelles or emulsions in water, which can reduce the bioavailable  
35 fraction even though it appears that the substance is dissolved. This can cause data  
36 interpretation problems for fish BCF tests, and means that the  $K_{ow}$  might not be  
37 measurable using the shake-flask or slow stirring methods (see Section R.7.1 for further  
38 details of how the  $K_{ow}$  can be measured or estimated).

39 The quality of the relationship between log  $K_{ow}$  estimates and bioconcentration depends  
40 on the category and specific type of surfactant involved. Other measures of  
41 hydrophobicity such as the critical micelle concentration (CMC) might be more  
42 appropriate in some cases (e.g. Roberts & Marshall, 1995; Tolls & Sijm, 1995). Indeed, a  
43 general trend of increasing bioconcentration with decreasing values of the CMC can be  
44 observed, confirming that bioconcentration increases with hydrophobicity as for other

1 chemicals. Nevertheless, many straight alkyl chain surfactants are readily metabolised in  
2 fish, so that predicted BCFs may be overestimated (e.g. Tolls & Sijm, 1999; Tolls *et al.*,  
3 2000; Comber *et al.*, 2003). Therefore, the classification of the bioconcentration  
4 potential based on hydrophobicity measures (such as log  $K_{ow}$ ) should be used with  
5 caution. Correlations of the bioconcentration behaviour with physico-chemical  
6 parameters can be expected only if:

- 7 a. the rate of biotransformation is the same across a surfactant series, or
- 8 b. biotransformation does not play a role (e.g. for branched alkyl chains, where  
9 bioconcentration will increase with increasing chain length) (Tolls & Sijm,  
10 2000).

11 Measured BCF values are preferred.

12 An additional factor to consider is that commercial surfactants tend to be mixtures of  
13 chain lengths, each with its own BCF (e.g. Tolls, *et al.*, 1997 & 2000). The guidance for  
14 complex mixtures is therefore also applicable for commercial surfactants. If tests are  
15 needed it is recommended that they should be done with a single chain length where  
16 possible.

### 17 **Organic substances that do not partition to lipid**

18 Bioconcentration is generally considered as a partitioning process between water and  
19 lipid, and other distribution compartments in the organism can usually be neglected (the  
20 water fraction may play a role for water-soluble substances (de Wolf *et al.*, 1994)).  
21 However, proteins have been postulated as a third distribution compartment contributing  
22 to bioconcentration (SCHER, 2005), and may be important for certain types of chemicals  
23 (e.g. perfluorosulphonates, organometallic compounds such as alkyl- or glutathione-  
24 compounds, for instance methyl mercury, methyl arsenic, etc.). Evidence for such a role  
25 may be available from mammalian toxicokinetics studies.

26 Protein binding in biological systems performs a number of functions (e.g. receptor  
27 binding to activate and/or provoke an effect; binding for a catalytical reaction with  
28 enzymes; binding to carrier-proteins to make transport possible; binding to  
29 obtain/sustain high local concentrations above water solubility, such as oxygen binding  
30 to haemoglobin, etc.). In some circumstances, binding may lead to much higher local  
31 concentrations of the ligand than in the surrounding environment.

32 Nevertheless, the picture may be complicated because the process is not necessarily  
33 driven purely by partitioning (binding sites may become saturated and binding could be  
34 either reversible or irreversible). Indeed, it has been postulated that measured BCFs  
35 may be concentration dependant due to protein binding (SCHER, 2004). In other words,  
36 bioconcentration is limited by the number of protein binding sites rather than by lipid  
37 solubility and partitioning. Further work is needed to conceptualize how protein binding  
38 might give rise to food chain transfer across trophic levels, and assess its relative  
39 contribution compared with other (lipids and water) distribution mechanisms.

40 In the absence of such studies, elimination studies can be useful for comparing half-lives  
41 of chemicals that may accumulate via proteins with those for other chemicals that are  
42 known to be bioaccumulative.

## R.7.11 Effects on terrestrial organisms

### R.7.11.1 Introduction

Substances introduced into the environment may pose a hazard to terrestrial organisms and as such potentially have deleterious effects on ecological processes within natural and anthropogenic ecosystems. Due to the complexity and diversity of the terrestrial environment, a comprehensive effect assessment for the whole compartment can only be achieved by a set of assessment endpoints covering (i) the different routes by which terrestrial organisms may be exposed to substances (i.e. air, food, pore water, bulk-soil) and (ii) the most relevant taxonomic and functional groups of terrestrial organisms (micro-organism, plants, invertebrates, vertebrates) being potentially affected (CSTEE, 2000). The scope of the terrestrial effect assessment under the adopted REACH regulation is restricted to soil organisms in a narrow sense, i.e. on non-vertebrate organisms living the majority of their lifetime within the soil and being exposed to substances via the soil pathway and in line with the previous practice in the environmental risk assessment of new and existing substances in the EU. The actual scoping of the effect assessment for the terrestrial environment does not include (EU, 2003):

- terrestrial invertebrates living above-ground (e.g. ground dwelling beetles),
- terrestrial vertebrates living a part of their lifetime in soils (e.g. mice),
- groundwater organism (invertebrates and micro-organism), and
- adverse effects on soil functions that are only indirectly linked to the biota in soils (e.g. buffering capacity, formation of soil structure, water cycle etc.) It should be stressed however that by addressing direct effects on soil biota, potential effects on these soil functions indirectly addressed (see below).

As for terrestrial vertebrates living above-ground reference is made to the relevant sections for mammals (Sections R.7.2 to R.7.7) and birds (Section [R.7.10.16](#)).

The importance of assessing the potential adverse effects on soil organisms within the environmental risk assessment of substances is at least two-fold:

First, there is a general concern with regard to the exposure of soil organisms, as soils are a major sink for anthropogenic substances emitted into the environment. This is especially pivotal for persistent substances with an inherent toxic potential, which may accumulate in soils and thereby posing a long-term risk to soil organisms. Second, protection of specific soil organisms is critical due to their role in maintaining soil functions, e.g. the breakdown of organic matter, formation of soil structure and cycling of nutrients. In view of the latter, protection goals for soil can both relate to structure (diversity and structure of soil organisms communities) and functions (ecosystem functions provided by soil organism communities) of soil biota.

Valuable contributions for assessing the effect of a specific substance on soil organisms may be obtained from endpoints such as physical-chemical properties (Section R.7.1) and (bio-) degradation (Section R.7.9) providing information on the fate of the substance. In the absence of experimental data on soil organisms data can be used that were generated on aquatic organisms (Equilibrium Partitioning Method, EPM);

1 information requirements for aquatic organisms under REACH are addressed in Section  
2 R.7.8. However, due to the high level of uncertainty regarding the area of validity of the  
3 EPM, this approach should be limited to screening purposes only.

4 The complexity, heterogeneity and diversity of soil ecosystems are the major challenge  
5 when assessing potential adverse effects of substances on soil organisms. This holds true  
6 both regarding soil as substrate, and thus exposure medium, and the biota communities  
7 living in the soil. Spatial and temporal fluctuations in environmental conditions, i.e.  
8 climate increase the complexity of assessing potential effects in soil.

## 9 **Soil**

10 If considered as an exposure medium soil is characterised by a highly complex, three-  
11 phase system consisting of non-organic and dead organic matter, soil pore water and  
12 pore space (soil air). Substances released to the soil system are exposed to different  
13 physical, chemical and biological processes that may influence their fate (e.g.  
14 distribution, sorption/ de-sorption, transformation, binding and breakdown) and as such  
15 their bioavailability (see below) and effects on soil organisms. Moreover, structure,  
16 texture and biological activity greatly varies between different soil types and sites,  
17 respectively and soil properties even may alter due to changing environmental conditions  
18 (e.g. changes in organic matter content or amount of soil pores). As a consequence, the  
19 comparability of fate and effect data between different soils is limited, making  
20 extrapolations cumbersome. Hence, the selection of appropriate soils for biological  
21 testing or monitoring procedures is a crucial step when assessing the effects on soil  
22 organisms. Furthermore, standardisation of soil effect data to a given soil parameter  
23 (e.g. organic matter content or clay content) is common practice.

## 24 **Soil organisms**

25 Typical soil organism communities in the field are highly diverse regarding their  
26 taxonomic composition and structured by complex inter-relationships (e.g. food-webs).  
27 Due to the diversity of species, a multitude of potential receptors for adverse effects of  
28 toxic substances exist in soils differing in size, soil micro-habitat, physiology and life-  
29 history. Consequently, a set of indicators representing three soil organism groups of  
30 major ecological importance and covering all relevant soil exposure pathways is required  
31 for a comprehensive effect assessment of substances in soils (see [Table R.7.11–1](#)).

32

1 **Table R.7.11—1 Major groups of soil organisms to be considered in effect**  
2 **assessment**

| Organism group  | Ecological process   | Soil exposure pathway   | Important taxa                 |
|-----------------|--|---|--------------------------------|
| Plants          | Primary production   | Mainly soil pore water (by root uptake)   | All higher plants              |
| Invertebrates   | Breakdown of organic matter<br>Formation of soil structure | Diverse and multiple uptake routes (soil pore water, ingestion of soil material, soil air, secondary poisoning) | Earthworms, springtails, mites |
| Micro-organisms | Re-cycling of nutrients                                    | Mainly soil pore water  | Bacteria, protozoa, fungi      |

3

#### 4 **Soil bioassay**

5 Soil bioassays are at present the most important method to generate empirical  
6 information on the toxicity of substances to soil organisms. Such bioassays are  
7 conducted by exposing test organisms to increasing concentrations of the test substance  
8 in soil, under controlled laboratory conditions. Short-term (e.g. mortality) or long-term  
9 (e.g. inhibition of growth or reproduction) toxic effects are measured. Ideally, toxicity  
10 testing results reveal information on the concentration-effect relationship and allow for  
11 the statistical derivation of defined Effect Concentrations (EC<sub>x</sub>, i.e. effective  
12 concentration resulting in x % effect) and/ or No Observed Effect Concentrations  
13 (NOEC). By convention, EC<sub>x</sub> and NOEC values generated by internationally standardised  
14 test guidelines (OECD, ISO) offer the most reliable toxicity data. However, only a limited  
15 number of standard test guidelines for soil organism are at present available, a fact that  
16 mirrors the generally limited data-base on the toxicity of substances towards soil  
17 organisms.

#### 18 **Bioavailability**

19 By addressing bioavailability of substances in soil, a potential method to deal with the  
20 diversity and complexity of soils is provided. Bioavailability considers the processes of  
21 mass transfer and uptake of substances into soil-living organisms which are determined  
22 by substance properties (key parameter: water solubility, K<sub>oc</sub>, vapour pressure), soil  
23 properties (with key parameter: clay content, organic matter content, pH-value, cation  
24 exchange capacity) and the biology of soil organisms (key parameter: micro-habitat,  
25 morphology, physiology, life-span). The practical meaning for effect assessment of both  
26 organic substances and metals is the observation that not the total loading rate, but only  
27 the bioavailable fraction of a substance in soil is decisive for the observed toxicity.  
28 Although being subject to extensive research activities in the past decade, there is  
29 actually no general approach for assessing the bioavailability of substances in soils.  
30 Major difficulties are the differences and the restricted knowledge about exposure  
31 pathways relevant for soil organisms and the fact that bioavailability is time-dependent.  
32 The latter phenomenon is commonly described as a process of "ageing" of substances in  
33 soil: Due to increasing sorption, binding and incorporation into the soil matrix,

1 bioavailability and consequently toxicity changes (mostly decreases) with time.  
2 Additional factors like climate conditions and land use may also influence bioavailability.  
3 Nonetheless, bioavailability should be critically considered when interpreting existing soil  
4 toxicity data as well as during the design of new studies.

#### 5 **R.7.11.1.1 Objective**

6 The overall objective of the effect assessment scheme proposed in this section is to  
7 gather adequate (i.e. reliable and relevant) information on the inherent toxic potential of  
8 specific substances to soil living organisms in order to:

- 9 • Identify if, and if so, which of the most relevant groups of soil organisms may  
10 potentially be adversely affected by a specific substance when emitted into  
11 the soil compartment, and to
- 12 • Derive a definite, scientifically reliable soil upper threshold concentration of no  
13 concern (Predicted No Effect Concentration for soil - PNEC<sub>soil</sub>) for those  
14 substances, for which adverse effects on soil organisms are to be expected.

15 Based on the information and relevant toxicity data gathered during effect assessment,  
16 the derivation of the PNEC<sub>soil</sub> for a specific substance follows the general hazard  
17 assessment schemes as presented in a flow-chart of Section [R.7.11.6.3](#). Comparison of  
18 the PNEC<sub>soil</sub> with the respective Predicted Environmental Concentration expected for soil  
19 (PEC<sub>soil</sub>) from relevant emission scenarios will finally lead to a conclusion concerning the  
20 risk to organisms living in the soil compartment (risk characterisation). A risk identified  
21 on the basis of a PEC/PNEC comparison can demonstrate the need for a more refined  
22 risk-assessment (either on the PEC or PNEC side), or – in cases where there are no  
23 options for further refinement - to risk management decisions.

#### 24 **R.7.11.2 Information requirements**

##### 25 **R.7.11.2.1 Standard information requirements**

26 Article 10 of REACH presents the information that should be submitted for registration  
27 and evaluation of substances. In Article 12 the dependence of the information  
28 requirements on production volume (tonnage) is established in a tiered system,  
29 reflecting that potential exposure increases with volume.

30 Annexes VII-X to REACH specify the standard information requirements (presented in  
31 column 1). In addition, specific rules for their adaptation (presented in column 2) are  
32 included. These annexes set out the standard information requirements, but must be  
33 considered in conjunction with Annex XI to REACH, which allows variation from the  
34 standard approach. Annex XI to REACH contains general rules for adaptations of the  
35 standard information requirements that are established in Annexes VII to X.

36 Furthermore, generation of data for the PBT/vPvB assessment is required, where a  
37 registrant, while carrying out the CSA, cannot draw an unequivocal conclusion on  
38 whether the criteria in Annex XIII to REACH are met or not and identifies that terrestrial  
39 (soil) toxicity data would take the PBT/vPvB assessment further. This obligation applies  
40 for all  $\geq 10$  tpa registrations (see Chapter R.11 of the *Guidance on IR&CSA* for further  
41 details).

1 The following represent the specific requirements related to terrestrial (soil) toxicity  
2 testing:

3 Information requirements (column 1) and rules for adaptation of the standard  
4 information requirements (column 2) of the Annexes VII-X)

5 a) Annex VII (Registration tonnage >1 t/y -<10 t/y)

6 No terrestrial effects testing is required at this registration tonnage

7

8 b) Annex VIII (Registration tonnage >10 t/y)

9 No terrestrial effects testing is required at this registration tonnage

10

11 c) Annex IX (Registration tonnage >100 t/y)

12 Column 1 of this Annex establishes the standard information required for all substances  
13 manufactured or imported in quantities of 100 tonnes or more in accordance with Article  
14 12 (1) (d).

| Column 1                                      | Column 2   |
|---|--|
| Standard Information Required                 | Specific rules for adaptation from Column 1  |
| 9.2.3. Identification of degradation products | Unless the substance is readily biodegradable  |
| 9.4. Effects on terrestrial organisms         | 9.4. These studies do not need to be conducted if direct and indirect exposure of the soil compartment is unlikely.<br><br>In the absence of toxicity data for soil organisms, the EPM method may be applied to assess the exposure to soil organisms. The choice of the appropriate tests depends on the outcome of the chemical safety assessment.<br><br>In particular for substances that have a high potential to adsorb to soil or that are very persistent, the registrant shall consider long-term toxicity testing instead of short-term. |
| 9.4.1. Short-term toxicity to invertebrates   |  |
| 9.4.2. Effects on soil micro-organisms        |  |
| 9.4.3. Short-term toxicity to plants          |  |

15

1 *Identification and/or assessment of degradation products*

2 These data are only required if information on the degradation products following  
3 primary degradation is required in order to complete the Chemical Safety Assessment.

4 **Column 2:** "Unless the substance is readily degradable"

5 In these circumstances, it may be considered that any degradation products formed  
6 during such degradation would themselves be sufficiently rapidly degraded as not to  
7 require further assessment.

8 *Effects on terrestrial organisms*

9 **Column 2:** "these tests do not need to be conducted if direct and indirect exposure of  
10 soil compartment is unlikely."

11 If there is no exposure of the soil, or the exposure is so low that no refinement of the  
12  $PEC_{local}$  or  $PEC_{regional}$ , or  $PNEC_{soil\ organisms}$  is required, then this test may not be necessary.  
13 In general, it is assumed that soil exposure will occur unless it can be shown that there  
14 is no sludge application to land from exposed STPs and that aerial deposition are  
15 negligible and the relevance of other exposure pathways such as irrigation and/or  
16 contact with contaminated waste is unlikely.

17 In the case of readily biodegradable substances which are not directly applied to soil it is  
18 generally assumed that the substance will not enter the terrestrial environment and as  
19 such there is no need for testing of soil organisms is required. Furthermore, other  
20 parameters (e.g. low log  $K_{oc}/P_{ow}$ ) should be considered regarding the exposure pathway  
21 via STP sludge. In case of aerial deposition, other aspects such as photostability, vapour  
22 pressure, volatility, hydrolysis etc, should be taken into consideration.

23 **Column 2:** "In the absence of toxicity data for soil organisms, the Equilibrium  
24 Partitioning Method may be applied to assess the hazard to soil organisms. The choice of  
25 the appropriate tests depends on the outcome of the Chemical Safety Assessment."

26 In the first instance, before new terrestrial effects testing is conducted, a  $PNEC_{soil}$  may be  
27 calculated from the  $PNEC_{water}$  using Equilibrium Partitioning. The results of this  
28 comparison can be incorporated into the Chemical Safety Assessment and may help  
29 determine which, if any of the terrestrial organisms detailed in the standard information  
30 requirements should be tested.

31

32 **Column 2:** "In particular for substances that have a high potential to adsorb to soil or  
33 that are very persistent, the registrant shall consider long-term toxicity testing instead of  
34 short-term."

35 Some substances present a particular concern for soil, such as those substances that  
36 show a high potential to partition to soil, and hence may reach high concentrations, or  
37 those that are persistent. In both cases long-term exposure of terrestrial organisms is  
38 possible and the registrant should consider whether the long-term terrestrial effects  
39 testing identified in Annex X may be more appropriate. This is addressed in more detail  
40 in the integrated testing strategy in Section [R.7.11.6](#).

41

- 1 d) Annex X (Registration tonnage >1000 t/y)
- 2 Column 1 of this Annex establishes the standard information required for all substances  
3 manufactured or imported in quantities of 1000 tonnes or more in accordance with  
4 Article 12(1)(e). Accordingly, the information required in column 1 of this Annex is  
5 additional to that required in column 1 of Annex IX.

| Column 1  | Column 2   |
|---|--|
| Standard Information Required   | Specific rules for adaptation from Column 1  |
| 9.4. Effects on terrestrial organisms   | 9.4. Long-term toxicity testing shall be proposed by the registrant if the results of the chemical safety assessment according to Annex I indicates the need to investigate further the effects of the substance and/or degradation products on terrestrial organisms. The choice of the appropriate test(s) depends on the outcome of the chemical safety assessment.<br><br>These studies do not need to be conducted if direct and indirect exposure of the soil compartment is unlikely. |
| 9.4.4. Long-term toxicity testing on invertebrates, unless already provided as part of Annex IX requirements. |  |
| 9.4.6. Long-term toxicity testing on plants, unless already provided as part of Annex IX requirements.        |  |

- 6
- 7 *Effects on terrestrial organisms*
- 8 **Column 2:** "These tests need not be conducted if direct and indirect exposure of soil  
9 compartment is unlikely."
- 10 If there is no exposure of the soil, or the exposure is so low that no refinement of the  
11  $PEC_{local}$  or  $PEC_{regional}$ , or  $PNEC_{soil\ organisms}$  is required, then this test may not be necessary.  
12 In general, it is assumed that soil exposure will occur unless it can be shown that there  
13 is no sludge application to land from exposed STPs and that aerial deposition are  
14 negligible and the relevance of other exposure pathways such as irrigation and/or  
15 contact with contaminated waste is unlikely.
- 16 In the case of readily biodegradable substances which are not directly applied to soil it is  
17 generally assumed that the substance will not enter the terrestrial environment and as  
18 such there is no need for testing of soil organisms is required.
- 19 **Column 2:** "Long-term toxicity testing shall be proposed by the registrant if the results  
20 of the chemical safety assessment according to Annex I indicate the need to investigate  
21 further the effects of the substance and/or degradation products on soil organisms. The  
22 choice of the appropriate test(s) depends on the outcome of the chemical safety  
23 assessment"

1 These tests need not be proposed if there is no risk to the soil compartment identified in  
2 the chemical safety assessment such that a revision of the PNEC<sub>soil</sub> is not required.  
3 Where further information on terrestrial organism toxicity is required, either on the  
4 substance or on any degradation products, the number and type of testing will be  
5 determined by the chemical safety assessment and the extent of the revision to the  
6 PNEC<sub>soil</sub> required.

### 7 **PBT/vPvB assessment**

8 In the context of PBT/vPvB assessment, if the registrant cannot derive a definitive  
9 conclusion (i) ("The substance does not fulfil the PBT and vPvB criteria") or (ii) ("The  
10 substance fulfils the PBT or vPvB criteria") in the PBT/vPvB assessment using the  
11 relevant available information, he must, based on Section 2.1 of Annex XIII to REACH,  
12 generate the necessary information for deriving one of these conclusions, regardless of  
13 his tonnage band (for further details, see Chapter R.11 of the *Guidance on IR&CSA*). In  
14 such a case, the only possibility to refrain from testing or generating other necessary  
15 information is to treat the substance "as if it is a PBT or vPvB" (see Chapter R.11 of the  
16 *Guidance on IR&CSA* for details).

### 17 **R.7.11.3 Information and its sources**

18 Different types of information are relevant when assessing terrestrial exposure and  
19 subsequent toxicity to soil organisms. Useful information includes chemical and physical  
20 properties of substances and test systems as well as available testing data (*in vitro* and  
21 *in vivo*) and results from non-testing methods, such as the Equilibrium Partitioning  
22 Method. Sources of ecotoxicity data including terrestrial data have been listed in Chapter  
23 R3. Additional useful databases include US EPA ECOTOX database  
24 (<http://cfpub.epa.gov/ecotox/>) and OECD Screening Information DataSet (SIDS) for  
25 high volume chemicals  
26 (<http://www.chem.unep.ch/irptc/sids/ocedsids/indexchemic.htm>).

27 Physical and chemical data on the test substance can assist with experimental design  
28 and provide information on the endpoint of interest. The following information is useful  
29 for designing the soil test and identifying the expected route of exposure to the  
30 substance: structural formula, purity, water solubility, n-octanol/water partition  
31 coefficient (log K<sub>ow</sub>), soil sorption behaviour, vapour pressure, chemical stability in water  
32 and light and biodegradability.

### 33 **R.7.11.3.1 Laboratory data**

#### 34 **Non-testing data**

35 There is limited terrestrial toxicity data available for most substances. In the absence of  
36 terrestrial data, one option is to generate Q(SAR) predictions. General guidance on the  
37 use of (Q)SAR is provided in Section R.4.3.2.1 and specifically for aquatic (pelagic)  
38 toxicity in Section R.7.8. However at present there are no Q(SAR)s for soil ecotoxicology  
39 that have been well characterised. For example there are a few Q(SAR)s for earthworms,  
40 but these have not been fully validated (Van Gestel *et al.*, 1990). Therefore terrestrial  
41 endpoint predictions using Q(SAR)s should be carefully evaluated, and only used as part  
42 of a *Weight-of-Evidence* approach (see [Figure R.7.11–1](#)).

1 Grouping of substances with similar chemical structures on the hypothesis that they will  
2 have a similar mode of action is a method which has been used in the past to provide  
3 non-testing data. The underlying idea is that when (testing-) effect-data are available for  
4 a substance within the (structural similar) group, these can be used to “predict” the  
5 toxicity of other substances in the same group. This method has been successfully used  
6 for PCBs and PAHs.

7 Another option is to estimate concentrations causing terrestrial effects from those  
8 causing effects on aquatic organisms. Equilibrium partitioning theory is based on the  
9 assumption that soil toxicity expressed in terms of the freely-dissolved substance  
10 concentration in the pore water is the same as aquatic toxicity. Further guidance on how  
11 to use the equilibrium partitioning method is provided in Section R.10.6.1 as well as in  
12 the ITS in Section [R.7.11.6](#).

### 13 **Testing data**

#### 14 *In vitro* data

15 There are no standardised test methods available at present, however there are a range  
16 of *in vitro* soil tests that may have been used to generate terrestrial endpoint data, and  
17 this information could be used as part of a *Weight-of-Evidence* approach (see [Figure](#)  
18 [R.7.11-1](#)). A useful review of *in vitro* techniques is provided in the CEH report, ‘Review  
19 of sublethal ecotoxicological tests for measuring harm in terrestrial ecosystems’  
20 (Spurgeon *et al.*, 2004).

#### 21 *In vivo* data

22 The officially adopted OECD and ISO test guidelines are internationally agreed testing  
23 methods, and therefore should ideally be followed to generate data for risk assessments.  
24 Further details have been provided in this section on the OECD and ISO standard test  
25 guidelines which are recommended to test the toxicity of substances to soil organisms.  
26 However, there are a range of other standard and non-standard tests available, which  
27 can also be used to generate terrestrial endpoint data. [Appendix R.7.11-1](#) includes a  
28 detailed list of terrestrial test methodologies, including several test methods that are  
29 currently under development. The data from non-standard methodologies will need to be  
30 assessed for their reliability, adequacy, relevance and completeness.

#### 31 OECD and ISO Test Guidelines

##### 32 i) Microbial Assays

33 Microorganisms play an important role in the break-down and transformation of organic  
34 matter in fertile soils with many species contributing to different aspects of soil fertility.  
35 Therefore, any long-term interference with these biochemical processes could potentially  
36 disrupt nutrient cycling and this could alter soil fertility. A NOEC/ECx from these tests  
37 can be considered as a long-term result for microbial populations.

1 *Soil Micro-organisms, Nitrogen Transformation Test – OECD 216 (OECD, 2000a); ISO*  
2 *14238 (ISO, 1997a)*

3 *Soil Micro-organisms, Carbon Transformation Test – OECD 217 (OECD, 2000b) ; ISO*  
4 *14239(ISO, 1997b)*

5 The carbon and nitrogen transformation tests are both designed to detect long-term  
6 adverse effects of a substance on the process of carbon or nitrogen transformation in  
7 aerobic soils over at least 28 days.

8 For most non-agrochemicals the nitrogen transformation test is considered sufficient as  
9 nitrate transformation takes place subsequent to the degradation of carbon-nitrogen  
10 bonds. Therefore, if equal rates of nitrate production are found in treated and control  
11 soils, it is highly probable that the major carbon degradation pathways are intact and  
12 functional.

13 Further ISO-standard methodologies are available, however since no corresponding  
14 OECD guideline exists, these methods are less commonly used than the 2 microbial  
15 assays mentioned above.

16 *Determination of potential nitrification, a rapid test by ammonium oxidation – ISO 5685*  
17 *(ISO, 2004a)*

18 Ammonium oxidation is the first step in autotrophic nitrification in soil. The method is  
19 based on measurement of the potential activity of the nitrifying population as assessed  
20 by the accumulation of nitrite over a short incubation period of 6 hours. The method  
21 does not assess growth of the nitrifying population. Inhibitory doses are calculated.

22 *Determination of abundance and activity of the soil micro-flora using respiration curves –*  
23 *ISO 17155 (ISO, 2002)*

24 This method is used to assess the effect of substances on the soil microbial activity by  
25 measuring the respiration rate (CO<sub>2</sub> production or O<sub>2</sub> consumption). The substance may  
26 kill the micro-flora, reduce their activity, enhance their vitality or have no effect (either  
27 because the toxicity of the substances is low or some species are replaced by more  
28 resistant ones). EC10/NOEC and EC50 are determined when toxicity is observed.

29 ii) Invertebrate Assays

30 *Earthworm acute toxicity test – OECD 207 (OECD, 1984); ISO 11268-1 (ISO, 1993)*

31 The test is designed to assess the effect of substances on the survival of the earthworms  
32 *Eisenia* spp. Although the OECD guideline provides details of a filter paper contact test,  
33 this should only be used as a screening test, as the artificial soil method gives data far  
34 more representative of natural exposure of earthworms to substances without requiring  
35 significantly more resources to conduct. Mortality and the effects on biomass are  
36 determined after 2 weeks exposure, and these data are used to determine the median  
37 lethal concentration (LC50). Although *Eisenia* spp. are not typical soil species, as they  
38 tend to occur in soil rich in organic matter, its susceptibility to substances is considered  
39 to be representative of soil fauna and earthworm species. *Eisenia* spp. is also relatively  
40 easy to culture in lab conditions, with a short life cycle, and can be purchased  
41 commercially.

1 *Earthworm reproduction test – OECD 222 (OECD, 2004a); ISO 11268-2 (ISO, 1998)*

2 The effects of substances on the reproduction of adult compost worms, *Eisenia* spp. is  
3 assessed over a period of 8 weeks. Adult worms are exposed to a range of  
4 concentrations of the test substance mixed into the soil. The range of test concentrations  
5 is selected to encompass those likely to cause both sub-lethal and lethal effects.  
6 Mortality and growth effects on the adult worms are determined after 4 weeks of  
7 exposure, and the effects on reproduction assessed after a further 4 weeks by counting  
8 the number of offspring present in the soil. The NOEC/ECx is determined by comparing  
9 the reproductive output of the worms exposed to the test substance to that of the  
10 control.

11 *Enchytraeid reproduction test – OECD 220 (OECD, 2004b) ; ISO 16387 (ISO, 2004b)*

12 Enchytraeids are soil dwelling organisms that occur in a wide range of soils, and can be  
13 used in laboratory tests as well as semi-field and field studies. The OECD guideline  
14 recommends the use of *Enchytraeus albidus*, which is easy to handle and breed and their  
15 generation time is significantly shorter than that of earthworms. The principle of the test  
16 is the same as for the earthworm reproduction test: adult worms are exposed to a range  
17 of concentrations of the test substance mixed into the soil. The duration of the  
18 reproductive test is 6 weeks, and mortality and morphological changes in the adults are  
19 determined after 3 weeks exposure. The adults are then removed and the number of  
20 offspring, hatched from the cocoons in the soil is counted after an additional 3 weeks  
21 exposure. The NOEC/ECx is determined by comparing the reproductive output of the  
22 worms exposed to the test substance, to the reproductive output of the control worms.

23 *Inhibition of reproduction of Collembola (Folsomia candida) – ISO 11267(ISO, 1999a)*

24 Collembolans are the most numerous and widely occurring insects in terrestrial  
25 ecosystems. This is one of the main reasons for why they have been widely used as  
26 bioindicators and test organisms for detecting the effects of environmental pollutants.  
27 The ISO guideline recommends the use of *Folsomia candida*, which reproduces by  
28 asexual reproduction and resides primarily in habitats rich in organic matter such as pot  
29 plants and compost heaps. A treated artificial soil is used as the exposure medium and a  
30 NOEC/ECx for survival and off-spring production is determined after 21 days.

31 iii) Plant Assays

32 The most suitable standard methodology for plants to be used for industrial substances  
33 that are likely to be applied via sewage sludge is OECD 208 (OECD, 2006a) guideline,  
34 which assesses seedling emergence and seedling growth. The second standard method  
35 OECD 227 (OECD, 2006b) is more suitable for substances that are likely to deposit on  
36 the leaves and above-ground portions of plants and through aerial deposition. There is  
37 also a recent ISO test guideline ISO 22030 (ISO, 2005a)), which assesses the chronic  
38 toxicity of higher plants.

39 *Terrestrial Plant Test: Seedling emergence and seedling growth test – OECD 208 (OECD  
40 2006a); ISO 11269-2(ISO, 2005b)*

41 The updated OECD guideline is designed to assess the potential effects of substances on  
42 seedling emergence and growth. Therefore, it is specific to a part of the plants life-cycle  
43 and does not cover chronic effects or effects on reproduction, however it is assumed to  
44 cover a sensitive stage in the life-cycle of a plant and therefore data obtained from this

1 study have been used as estimates of chronic toxicity. Seeds are placed in contact with  
2 soil treated with the test substance and evaluated for effects following usually 14 to 21  
3 days after 50% emergence of the seedlings in the control group. Endpoints measured  
4 are visual assessment of seedling emergence, dry shoot weight (alternatively wet shoot  
5 weight) and in certain cases shoot height, as well as an assessment of visible  
6 detrimental effects on different parts of the plant. These measurements and  
7 observations are compared to those of untreated control plants, to determine the EC50  
8 and NOEC/EC10.

9 *Terrestrial plant test: Vegetative vigour test – OECD 227 (OEC, 2006b)*

10 This guideline is designed to assess the potential effects on plants following deposition of  
11 the test substance on the leaves and above-ground portions of plants. Plants are grown  
12 from seed usually to the 2-4 true leaf stage. Test substance is then sprayed on the plant  
13 and leaf surfaces at an appropriate rate. After application, the plants are then evaluated  
14 against untreated control plants for effects on vigour and growth at various time  
15 intervals through 21-28 days after treatment. Endpoints are dry or wet shoot weight, in  
16 certain cases shoot height, as well as an assessment of visible detrimental effects on  
17 different parts of the plant. These measurements are compared to those of untreated  
18 control plants.

19 *Soil Quality –Biological Methods – Chronic toxicity in higher plants – ISO 22030 (ISO,*  
20 *2005a)*

21 This ISO test guideline describes a method for determining the inhibition of the growth  
22 and reproductive capability of higher plants by soils under controlled conditions. Two  
23 species are recommended, a rapid cycling variant of turnip rape (*Brassica rapa*) and oat  
24 (*Avena sativa*). The duration of the tests has been designed to be sufficient to include  
25 chronic endpoints that describe the reproductive capability of test plants compared to a  
26 control group. The chronic toxicity of substances can be measured by preparing a  
27 dilution series of the test substance in standard control soils.

### 28 **R.7.11.3.2 (semi-) Field data**

29 Field tests are higher tier studies which provide an element of realism but also add  
30 complexity in interpretation. There are very few standardised methods for evaluating the  
31 ecotoxicological hazard potential of substances in terrestrial field ecosystems. An  
32 example of such guidance which has frequently been used is the ISO guideline 11268-3  
33 for the determination of effects of pollutants on earthworms in field situations (ISO,  
34 1999b) This approach aims to assess effects on population size and biomass for a  
35 particular species or group of species and there is guidance summarising the conduct of  
36 such studies (de Jong *et. al.* 2006).

#### 37 Gnotobiotic laboratory tests

38 Gnotobiotic laboratory tests are relatively similar to single-species test and are run under  
39 controlled conditions. Usually a few species (2-5), either from laboratory cultures or  
40 caught in the field are exposed together in an artificial or (often sieved) field soil.  
41 Recently much work has been done with a gnotobiotic system called the Ohio type  
42 microcosm (Edwards *et al.*, 1998), which ranges in complexity between laboratory tests  
43 and terrestrial model ecosystems (CSTEE, 2000).

## 1 Terrestrial microcosms/mesocosms

2 Terrestrial microcosms/mesocosms can be used as integrative test methods in which fate  
3 and effect parameters are investigated at the same time and under more realistic field  
4 conditions. The Terrestrial Model Ecosystem (TME) is the only multi-species test that has  
5 a standardised guideline (ASTM, 1993). TMEs are small enough to be replicated but large  
6 enough to sustain soil organisms for a long period of time (Römbke *et al.*, 1994). TMEs  
7 can be used to address the effects on ecosystem structure and function which is not  
8 usually possible with single species tests. When TME's studies are conducted in the  
9 laboratory, they use intact soil cores extracted from a field site and therefore contain  
10 native soil communities. The degree of environmental relevance of these indoor TME's is  
11 therefore intermediate between laboratory and field studies.

12 Typically, in TME's after an acclimatisation period, 4-8 replicates are treated with  
13 increasing concentrations of the test-substance or left untreated as controls. They are  
14 then sampled at intervals for structural (plant biomass, invertebrate populations) or  
15 functional (litter decomposition, microbial activity) parameters. Such an approach may  
16 provide a link to effects to the field but under more controlled conditions (Knacker *et al.*,  
17 2004). The statistical analysis of TME data is dependent on the number and inter-  
18 relatedness of the endpoints measured. If there are many endpoints measured a  
19 multivariate analysis to derive a single effect threshold for the whole system may be  
20 appropriate. Due to the complexity of the data obtained in a TME, a standard "one-suits-  
21 all" statistical method to generate end-points from these studies cannot be provided.  
22 Expert judgement is required.

## 23 Field Studies

24 At present there are no standardised test methods for designing field studies to assess  
25 the hazard potential of substances for multiple species. As such field study methodology  
26 tends to be specifically designed tests for a particular substance and is difficult to  
27 reproduce. Dose response relationships are often lacking (CSTEE, 2000). However, field  
28 studies are the most accurate assessment of the impact of a substance on soil function  
29 and structure under natural climatic conditions.

### 30 **R.7.11.4 Evaluation of available information for a given substance**

31 Existing relevant soil organism data may be derived from a variety of sources. Data  
32 used in the risk assessments according to Council Directive 91/414/EEC and Council  
33 Regulation (EEC) No. 93/793 are considered to be of high quality and preferred over  
34 data available from other sources. The next highest quality category is well founded and  
35 documented data. These data should compromise a conclusive description of e.g. test  
36 conditions, tested species, test duration, examined endpoint(s), references, preferably  
37 be conducted according to the principles of Good Laboratory Practice, as well as a  
38 justification why the provided data should be used. Further data of lower priority may  
39 be provided from publishes literature, and data retrieved from public databases.

#### 40 **R.7.11.4.1 Evaluation of laboratory data**

##### 41 **Non-testing data**

42 Preferably PNEC values should be derived using testing for the substance under  
43 evaluation but such data are not always available. If data can be derived via

1 extrapolation based on information from similar substances, e.g. using QSAR or SAR  
2 models, then these may be used as supportive evidence and to advice on how to  
3 proceed with further testing. For the terrestrial ecosystems there are no OECD or ISO  
4 guidelines on (Q)SAR models, although some simple models have been published in the  
5 open literature e.g. van Gestel and Ma (1992), Xu *et al.* (2000), Wang *et al.* (2000) and  
6 Sverdrup *et al.* (2002). In general, if the models indicate little toxicity for a substance  
7 based on information from similar substances, this can imply reduced testing; expert  
8 judgement is required in these cases.

9 If no terrestrial data exist, read-across from available aquatic toxicity data, using the  
10 EPM method can be considered, as supportive evidence. If there is an indication that a  
11 specific group of aquatic organism is more sensitive than other groups e.g. if aquatic  
12 plants display a lower EC50 than Daphnia, then further testing of terrestrial plants may  
13 be most appropriate. Care should be taken as the aquatic test does not cover the same  
14 species groups as in the terrestrial system.

15 For more extensive modelling the guidance described in Sections R.6.1 and R.6.2 should  
16 be followed.

## 17 **Testing data**

### 18 Test organisms

19 In general priority is given to test organisms specified in the OECD and ISO guidelines.  
20 Species tested under other official and peer-reviewed guidelines e.g. ASTM can also be  
21 employed, but their relevance should be examined.

22 Non-standard species can also be accepted. However, when employing these in deriving  
23 PNEC in the absence of standard studies, it should be ascertained that the test-species is  
24 properly identified and characterized, and that the test method is suitable and complies  
25 with the standard guidelines in critical points. For example, recovery of the control  
26 animals or survival in the control, maximum level of variability in test results, exposure  
27 duration, endpoints studied should comply with those specified in the official test  
28 guideline. In general the same criteria as described for test species selected according  
29 the official guidelines should be applied.

30 The test species should ideally cover different habitats and feeding modes in the soil as  
31 well as different taxonomic groups. For strongly adsorbing or binding substances soil-  
32 dwelling organisms that feed on soil particles (e.g. earthworms) are most relevant.  
33 However, also a specific mode-of-action that is known for a given substance may  
34 influence the choice of the test species (e.g. for substances suspected of having specific  
35 effects on arthropods a test with springtails is more appropriate than tests on other  
36 taxonomic groups).

37 If a concern is raised on the relevance of a species then an expert should be consulted.

### 38 Endpoints

39 In general priority is given to test endpoints specified in the OECD and ISO guidelines,  
40 unless a special mode-of-action is known. Endpoints under other official and peer-  
41 reviewed guidelines e.g. ASTM can also be employed, but their relevance should be  
42 considered.

1 Non-standard endpoints can also be accepted. However, these should be evaluated in  
2 relation to ecological relevance and must be properly identified and characterized in  
3 order to ensure that the endpoint is suitable and complies with the guidelines in critical  
4 points. For example, if the guideline requires sub-lethal endpoints for a species after  
5 long-term exposure then the corresponding non-standard endpoint should be sub-lethal  
6 and comply with the general outlines specified in the standard test guideline. If non-  
7 standard endpoints are very different from the standard endpoints then these must be  
8 scientifically justified. For example, an endpoint can be particularly sensitive or targeted to  
9 the mode-of-action for the substance in question. Screening endpoints such as  
10 behavioural responses, i.e. avoidance testing should not be interpreted in isolation. The  
11 criteria for reliability, e.g. uncertainty of non-standard endpoints should comply with  
12 those of standard endpoints.

13 If a concern is raised on the relevance of a species then an expert should be consulted.

#### 14 Exposure pathways

15 In general, exposure pathway should be as specified in the OECD and ISO guidelines,  
16 unless special pathways should be considered.

17 Non-standard test can also be accepted. If non-standard data are available then it  
18 should be considered whether the characteristics of the test substance scientifically  
19 justify the chosen exposure pathway. The exposure route is partly dependent on the  
20 physical-chemical nature of the substance and also influenced by species-specific life-  
21 strategy of the test organism. For strongly adsorbing or binding substances, preference  
22 should be given to test designs and test organisms that cover the exposure via ingestion  
23 or strong soil particle contact, as this is likely the most relevant exposure route for such  
24 substances. As mentioned in Section [R.7.11.3](#), some standard test methodologies  
25 include species with food exposure (earthworm reproduction, Enchytraeids and  
26 Collembola) while others have contact exposure only.

27 If a concern is raised on the relevance of the exposure regime then an expert should be  
28 consulted.

#### 29 Composition of soils and artificial-soils

30 In general, soils in effect testing should be chosen as specified in the OECD and ISO  
31 guidelines, unless special conditions are considered.

32 Non-standard soils can also be accepted. For soils the composition and the choice of soil  
33 type have a very large influence on the toxicity of many substances. Hence, if non-  
34 standard soils are used it should be considered whether the soil chosen represent a  
35 realistic worst-case-scenario for the tested substance. For most substances there is a  
36 lack of detailed knowledge about how the toxicity depends of the soil parameters; as  
37 such there is little reason to judge the reliability of available data solely based on the site  
38 of origin/geography. In general the main parameters driving the bioavailability of  
39 substances in soils are clay and organic matter (OM) content, Cation Exchange Capacity  
40 (CEC) and pH. For many metals CEC and pH have been shown to be main drivers,  
41 whereas for non-polar organics OM has been shown important. For non-standard  
42 artificial soil the source of organic matter can also heavily influence the result. Hence, if  
43 one of the soil parameters e.g. CEC or pH is very different from those outlined in the  
44 guideline or the habitat in question, then a scientific justification of the importance of

1 this derivation should be presented. Residual contaminants are generally not present in  
2 artificial substrates, but can be a potential confounding factor if natural soils are used for  
3 testing. This affects exposure considerations and is further described in Section  
4 [R.7.11.4.2](#).

5 If a concern is raised on the relevance of a species then an expert should be consulted.

#### 6 Method of spiking

7 In general soil tested should be as spiked as specified in the standard OECD and ISO  
8 guidelines, unless special conditions are considered.

9 If non-standard spiking methods are used, these should be scientifically justified. In  
10 general there are a variety of spiking methods including direct addition of the substance  
11 to soil, using water or a solvent carrier, application via sludge or direct spraying. Spiking  
12 soils tends to be problematic for poorly soluble substances (see also Aquatic Toxicity  
13 Section R.7.8.7.). The standard approach is to dissolve the test substance in a solvent  
14 and then to spike sand, blow-off the solvent and mix the sand into soil using different  
15 ratios of sand/soil to derive various test concentrations. The drawback with this  
16 technique is that even after hours/days of mixing, the substance may not be  
17 homogeneously mixed to the soil, but merely present as solid particles on the original  
18 sand. In some cases studies will have been carried out with the use of solubilisers. In  
19 these circumstances it is important to consider the change in bioavailability of the test-  
20 substance and also the potential impact of the solubiliser. Studies performed without  
21 solvents/solubilisers are preferred over studies with solvents/solubilisers.  
22 Solvent/solubiliser concentrations should be the same in all treatments and controls.

23 Bio-availability of substances in soil is known to change over time, aging of the  
24 substance in the soil after spiking (with or without solvents) is therefore to be  
25 considered. The appropriateness of the aging in studies to derive effect-endpoints  
26 depends on the use scenario and the type of risk assessment conducted with this  
27 endpoint. Expert judgement is as such required here. For metals and inorganic metal  
28 substances both short aging/equilibration times and high spiked metal concentrations in  
29 soils will accentuate partitioning of metals to the dissolved phase and increase the  
30 probability of exposure and/or toxicity via dissolved metals (Oorst *et al.*, 2006).  
31 Simulated aging and weathering processes may be desirable to take account of, but  
32 currently this is not included in standard test protocols.

33 Where a reasonable estimation of the exposure concentration cannot be determined then  
34 the test result should be considered with caution unless as part of a *Weight-of-Evidence*  
35 approach (see Section [R.7.11.5](#)).

#### 36 Duration of exposure

37 In general, the test duration should be as specified in the standard OECD and ISO  
38 guidelines, unless special conditions are considered.

39 For non-standard test methodologies it is important to ensure that the duration of  
40 exposure in the test is long enough for the test substance to be taken up by the test  
41 organisms. In chronic tests the duration should cover a considerable part of the lifecycle.  
42 Especially for strongly adsorbing substances it may take some time to reach equilibrium  
43 between the soil concentration in the test system and in the test organisms. If the

1 duration of the exposure is different from those in the corresponding guidelines, a  
2 scientific justification for the importance of this should provided or the study can be used  
3 in the *Weight of Evidence*.

4 If a concern is raised on the relevance of a species then an expert should be consulted.

#### 5 Feeding

6 In general the soil type and soil conditions used for the test should be chosen as  
7 specified in the OECD and ISO guidelines, unless special conditions are required.

8 In long-term tests, especially with reproduction or growth as endpoint, feeding of the  
9 test organisms is necessary. Generally the tests are designed in such a way that the food  
10 necessary for the test organisms during the study is added to the soil after spiking with  
11 the test substance. In standard test methodology, the food is not spiked with the test  
12 substance. For non-standard methods the food type depends on the test species. It has  
13 to be considered that any food added to the test system either periodically during the  
14 test period or only at test initiation may influence outcome of the study and as such the  
15 reliability of the data obtained.

16 Ad-libitum feeding, or the lack of such may influence the state of health of the test  
17 organisms and as such their ability to cope with (chemical-) stress. Different feeding  
18 regimes are therefore a source of variation on the expression of the effect parameter.

#### 19 Test design

20 In general the test-design should be as specified in the standard OECD and ISO  
21 guidelines, unless special conditions are required.

22 For standard test methodologies details of test design are normally well documented. To  
23 ensure the validity non-standard test methodology, these should to a large extent follow  
24 the specifications outlined in the standard guideline tests e.g. including sufficient  
25 concentrations and replications and positive and negative controls. For a proper  
26 statistical evaluation of the test results, the number of test concentrations and replicates  
27 per concentration are critical factors. If a solvent is used for the application of the test  
28 substance, an additional solvent control is necessary. The appropriate number of  
29 replicates to be included in a test is dependent on the statistical power required for the  
30 test. More guidance on statistical design is provided in the OECD (2006c). It is not a  
31 priori possible, to advice on what test design details are of key importance and which  
32 can be allowed to be missing before validity of the results becomes equivocal. If relevant  
33 information on test design is missing in non-standard test then they can only be used in  
34 a *Weight-of-Evidence* approach.

### 35 **R.7.11.4.2 Field data and model ecosystems**

#### 36 **Multi-species test**

37 There are no OECD or ISO guideline on terrestrial multi-species test systems.

38 Since not standardised and given their complexity multi-species test should be judged on  
39 a case-by-case basis and expert judgement is necessary to fully interpret the results.  
40 Several test-designs and evaluation of these have been published, ranging from  
41 standardised gnotobiotic systems (Cortet *et al.*, 2003) to tests including indigenous soils

1 and soil populations (Parmelee *et al.*, 1997, Knacker and van Gestel 2004). Fixed trigger  
2 values for acceptability of effects are not recommended as the impact of treatments can  
3 be significantly different depending on the test design. However, laboratory based multi-  
4 species studies should in general be given the same general consideration as the single  
5 species test, e.g. with regard to reliability and relevance. For terrestrial model  
6 ecosystems there may be a large natural variation inherent in the test systems  
7 compared to single species test. To address diversity and species interaction the multi-  
8 test systems should contain sufficient complex assemblages of species with diverse life  
9 strategies. In assessing the reliability of results from a model-ecosystems special  
10 attention should be given to the statistical evaluation and the capability of the test  
11 design to identify possible impact. Effects observed through time, whether permanent or  
12 transitory should be explored. Combinations of both univariate and multivariate analyses  
13 are preferred; guidance can be obtained from Morgan and Knäcker (1994), van den  
14 Brink & Braak (1999), Scott-Fordsmand & Damgaard (2006).

### 15 **Field testing**

16 In field trials, population level effects as opposed to effects on individuals are the desired  
17 goal or endpoint of the studies. The population effect on a species or group of species  
18 including time to recover should be analysed in comparison to control plots. Fixed  
19 trigger values for acceptability of effects are not recommended, as the impact of  
20 treatments can be significantly different for different organisms. Biological characteristics  
21 such as development stage, mobility of species and reproduction time can influence the  
22 severity of effects. Thus acceptability should be judged on a case-by-case basis and  
23 expert judgement is necessary to fully interpret field study results. Where significant  
24 effects are detected the duration of effects and range of taxa affected should be taken  
25 into consideration (Candolfi *et al.*, 2000).

#### 26 **R.7.11.4.3 Exposure considerations for terrestrial toxicity**

27 Before their use the exposure data should be validated in respect of their completeness,  
28 relevance and reliability. Guidance on how to evaluate exposure data will be developed  
29 in Section R.5.1. Consideration should be given to whether the substance being assessed  
30 can be degraded, biotically or abiotically, to give stable and/or toxic degradation  
31 products. Where such degradation can occur the assessment should give due  
32 consideration to the properties (including toxic effects) of the products that might arise.

#### 33 **R.7.11.4.4 Remaining uncertainty**

34 Soil is a very heterogeneous environment compartment where abiotic parameters and  
35 soil structural conditions can vary within very short distances; these introduce an extra  
36 dimension of variability into soil test. Therefore it is important to have a good  
37 characterisation of the media chosen in the test. In addition there is usually a larger  
38 variation around the individual results than from other media. For non-standard tests the  
39 variation in the toxicity results should be comparable to the one required in standard  
40 tests.

41 The available standardised test methods only deal with a few taxa of soil invertebrates.  
42 Therefore, not all specific effects of substances on the wide range of organisms normally  
43 present in soil may be covered by the available test methods. As these organisms may  
44 play an important role in the soil community, it may be relevant to consider results from

1 non-standard test designs in completing Chemical Safety Assessment. Further standard  
2 test methods may be developed and a need may exist to revise the soil safety  
3 assessment concept accordingly in future.

#### 4 **R.7.11.5 Conclusions on “Effects on Terrestrial Organisms”**

##### 5 **R.7.11.5.1 Concluding on suitability for Classification and Labelling**

6 There are no soil toxicity data requirements set out in Annex I to the Regulation (EC) No  
7 1272/2008 (CLP Regulation) .

8

##### 9 **R.7.11.5.2 Concluding on suitability for PBT/vPvB assessment**

10 There is a potential use for both short-term and long-term soil toxicity data in  
11 determining the Toxicity component of PBT. However, there are currently no criteria  
12 included in Section 1.1.3 of Annex XIII to REACH for soil toxicity and thus no specific  
13 data requirements.

14 Where data exist showing short or long-term toxicity to soil organisms using standard  
15 tests on soil invertebrates or plants, these should be considered along with other data in  
16 a *Weight-of-Evidence* approach to the toxicity criteria (Section 3.2.3 of Annex XIII to  
17 REACH).

##### 18 **R.7.11.5.3 Concluding on suitability for use in Chemical Safety 19 Assessment**

20 Soil toxicity data are used in the chemical safety assessment to establish a  $PNEC_{soil}$  as  
21 part of a quantitative assessment of risk to the soil compartment. Ideally, this will be  
22 calculated based on good quality data from long-term toxicity studies on soil organisms  
23 covering plants, invertebrates and micro-organisms. Where such data exist from studies  
24 conducted to standardised internationally accepted guidelines, these may be used  
25 directly to establish the  $PNEC_{soil}$ .

26 It must be recognized, however, that these type of data are rarely available, and may  
27 not be needed to characterize the risk for soil. In defining what can be considered as  
28 sufficiency of information, it is also necessary to have all available information on water  
29 solubility, octanol/water partitioning ( $\log K_{ow}$ ), vapour pressure, and biotic and abiotic  
30 degradation, and the potential for exposure

31 When soil exposure is considered negligible, i.e. where there is low likelihood of land  
32 spreading of sewage sludge, or aerial deposition of the substance and other pathways  
33 such as irrigation or contact with contaminated waste are equally unlikely, then neither a  
34 PEC, nor PNEC can or need be calculated and no soil toxicity data are necessary.

35 In general, the data available will be less than that required to derive a definitive PNEC  
36 for soil organisms. The following sections, nevertheless describe the circumstances  
37 where data-sets of differing quality and completeness can be considered ‘fit for the  
38 purpose’ of calculating a PNEC for the purposes of the chemical safety assessment.

39 Furthermore, a section on the *Weight-of-Evidence* approach is included at the end of this  
40 chapter, and guidance on testing strategies is presented in [Figure R.7.11–2](#) and [Figure](#)

1 [R.7.11–3](#) and a [Table R.7.11–2](#) in Section [R.7.11.6](#) (integrated testing strategy) of this  
2 report.

### 3 **Where no soil toxicity data are available**

4 There will be circumstances where no soil organism toxicity data are available. In making  
5 a judgment on whether soil organism toxicity data should be generated, and if so which  
6 these should be, all available data including those available on aquatic organisms should  
7 first be examined as part of a stepwise approach. Where the data available are sufficient  
8 to derive a PNEC for aquatic organisms, this PNEC can be used in a screening  
9 assessment for soil risks through the use of the EPM approach. If comparison of a  
10 PNEC<sub>soil</sub> derived by EPM from the aquatic PNEC, shows a PEC:PNEC ratio <1, then the  
11 information available may be sufficient to conclude the soil assessment. Where the  
12 adsorption is likely to be high, i.e. where the log K<sub>ow</sub> or Log K<sub>oc</sub> >5, the PEC:PNEC ratio is  
13 multiplied by 10. The use of the EPM method, however, provides only an uncertain  
14 assessment of risk and, while it can be used to modify the standard data-set  
15 requirements of Annex IX and X, it cannot alone be used to obviate the need for further  
16 information under this Annex. This will be further elaborated on in Section [R.7.11.6](#) and  
17 portrayed in tabular format in [Table R.7.11–2](#) of Section [R.7.11.6](#).

18 Where the PEC:PNEC ratio >1, then the information based on aquatic toxicity data alone  
19 (i.e. PEC/PNEC<sub>screen</sub>) is insufficient and soil toxicity data will need to be generated.

20 When the substance is also readily degradable, biotically or abiotically, however, and has  
21 a log K<sub>ow</sub> <5, this screening assessment showing no risk using aquatic toxicity data is  
22 sufficient to obviate the need for further information under Annex IX. In other  
23 circumstances, the derivation of a PNEC<sub>screen</sub> derived from aquatic toxicity data alone  
24 would be insufficient to derogate from Annex IX or X testing.

25 As is stated above, it will normally not be possible to derive a robust PNEC for the  
26 purposes of a soil screening assessment from acute aquatic toxicity testing showing no  
27 effect. This is, particularly true for poorly soluble substances. Where the water solubility  
28 is <1 mg/l, the absence of acute toxicity can be discounted as reliable indicator for  
29 potential effects on soil organism due to the low exposures in the test. The absence of  
30 chronic or long-term effects in aquatic organisms up to the substance solubility limit, or  
31 of acute effects within the solubility range above 10 mg/l can be used as part of a  
32 *Weight-of-Evidence* argument to modify/waive the data requirements of Annex IX and X.

33 Except in the specific situation described above, soil organism toxicity data are required  
34 as defined in Annex IX and X in order to derive or confirm a PNEC for the soil.

35 Normally, three L(E)C<sub>50</sub> values from standard, internationally accepted guidelines are  
36 required in order to derive a PNEC<sub>soil</sub>. The species tested should cover three taxonomic  
37 groups, and include plants, invertebrates and micro-organisms as defined in Annex IX.  
38 Normally, when new testing is required, these tests would be the OECD Guidelines Tests  
39 207 (Earthworm acute Toxicity), 208 (Higher Plant Toxicity) and 216 (Nitrogen  
40 Transformation). The PNEC can be derived by applying an assessment factor to the  
41 lowest L(E)C<sub>50</sub> from these test.

42 Before new testing is conducted, however, all available existing information should be  
43 gathered to determine whether the requirements of the Annexes are met. In general,

1 the data required should cover not just different taxa but also different pathways of  
2 exposure (e.g. feeding, surface contact), and this should be taken into account when  
3 deciding on the adequacy and relevance of the data. Thus earthworm testing allows  
4 potential uptake via each of surface contact, soil particle ingestion and porewater, while  
5 plant exposure will be largely via porewater.

6 In considering all the data available, expert judgment should be used in deciding  
7 whether the *Weight of Evidence* (see below) will allow specific testing to be omitted.

8 In general, where there is no toxicity L(E)C50 in the standard acute toxicity tests at >10  
9 mg/l, or no effects in chronic toxicity at the limit of water solubility, or the screening  
10 assessment based on EPM shows no concern, then a single short-term soil test on a  
11 suitable species would be adequate to meet the requirements of Annex IX. The soil PNEC  
12 would be derived by application of appropriate assessment factors to the aquatic data,  
13 and the soil short-term data, and the lowest value taken. Where the substance is highly  
14 adsorptive, e.g. where the  $\log K_{ow}/K_{oc} > 5$ , and/or the substance is very persistent in soil,  
15 this single test should be a long-term test. Substances with a half-life >180 days are  
16 considered to be very persistent in soil. This persistence would be assumed in the  
17 absence of specific soil data, unless the substance is readily degradable. The choice of  
18 test (invertebrate / plant / micro-organism) would be based on all the information  
19 available, but in the absence of a clear indication of selective toxicity, an invertebrate  
20 (earthworm or collembolan) test is preferred.

#### 21 **Acute or short-term soil organism toxicity data**

22 If data on soil toxicity are already available, this should be examined with respect to its  
23 adequacy (reliability and relevance). Normally, micro-organism or plant testing alone  
24 would not be considered sufficient, but would be considered as part of a *Weight-of-*  
25 *Evidence* approach. In circumstances where less than a full soil toxicity data-set is  
26 available, both the available soil data and the EPM modified aquatic toxicity data should  
27 be used in deriving the PNEC<sub>soil</sub>. In such circumstances, where the subsequent PEC:PNEC  
28 <1, this would constitute an adequate data-set and no further testing would be required

29 Where inhibition of sewage sludge microbial activity has been observed in Annex VIII  
30 testing, a test on soil microbial activity will additionally be necessary for a valid PNEC to  
31 be derived.

32 In all other circumstances, three short-term soil toxicity tests are needed to meet the  
33 requirements of Annex IX. Where the substance is highly adsorptive or very persistent  
34 as described above, the effect of long-term exposures should be estimated. Hence at  
35 least the invertebrate data should be derived from a long-term toxicity test, although  
36 other long-term toxicity data may be considered. It may be possible to show by *Weight*  
37 *of Evidence* from other tests, that no further specific test is needed. Where such an  
38 argument is made, it must be clearly documented in the chemical safety assessment.

39 The L(E)C50s are used to derive a PNEC using assessment factors.

#### 40 **Chronic or long-term soil organism toxicity data**

41 Chronic or long-term toxicity tests on plants and/or soil invertebrates conducted  
42 according to established guidelines can be used to derive a PNEC<sub>soil</sub>. The NOEC or  
43 appropriate EC<sub>x</sub> may be used with an appropriate assessment factor. Where such data

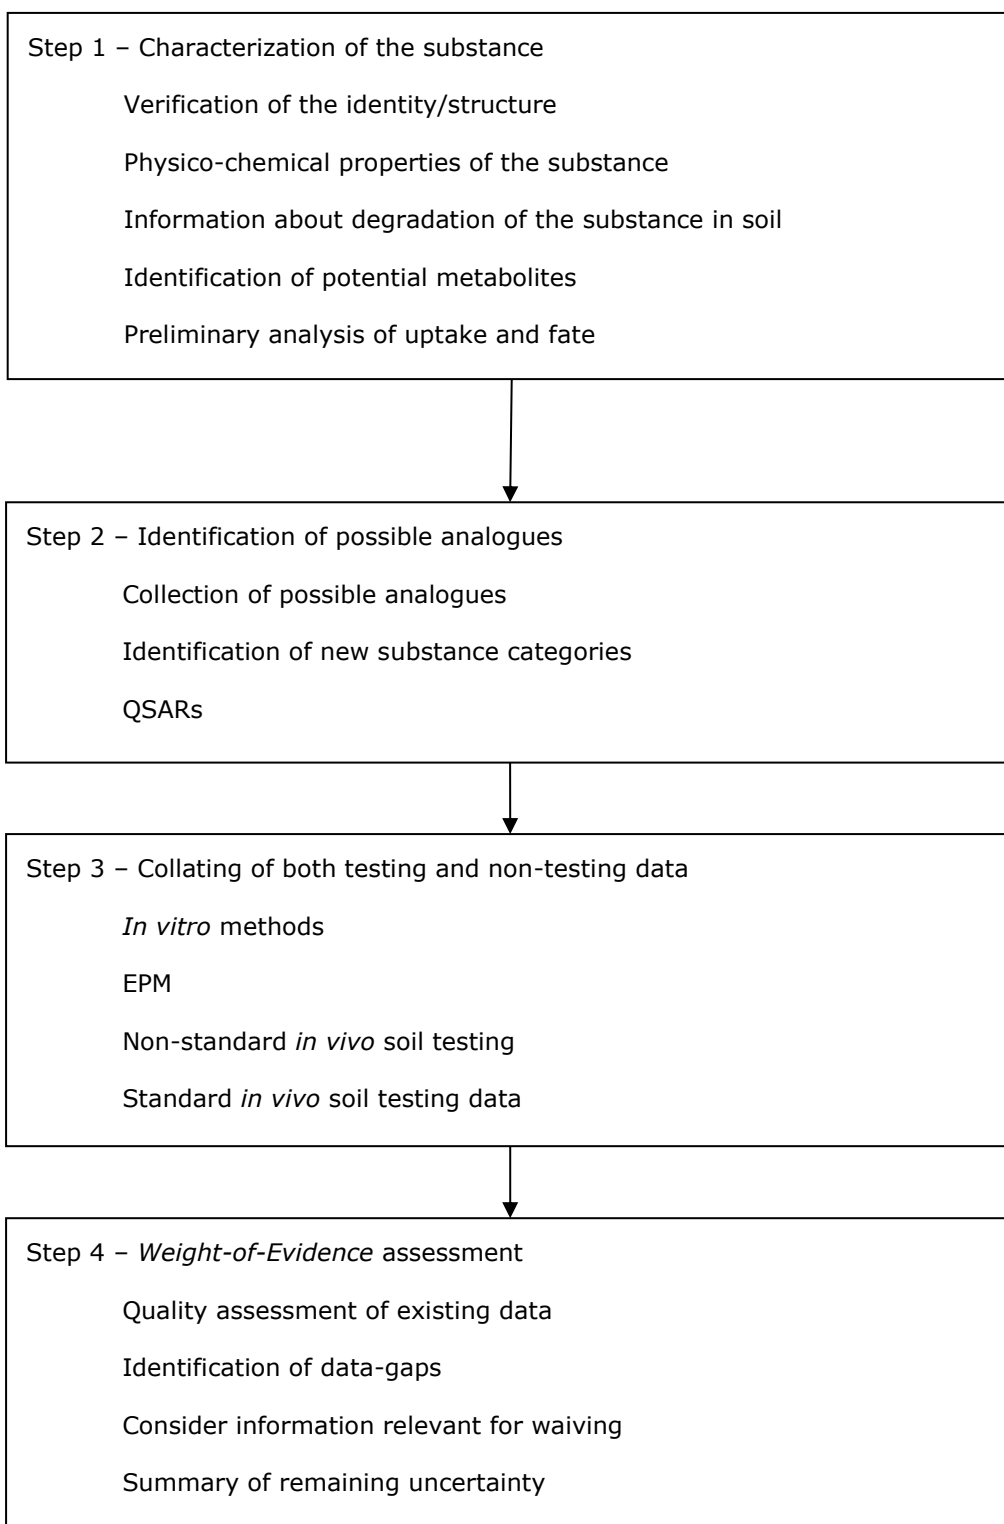

1 from chronic or long-term tests are available, they should be used in preference to  
2 short-term tests to derive the PNEC. In general, three long-term NOECs/EC<sub>x</sub>s are  
3 required, although the PNEC can be derived on two or one value with appropriate  
4 adjustment of the assessment factor. The tests should include an invertebrate  
5 (preferably earthworm reproduction test), a higher plant study and a study on micro-  
6 organisms (preferably on the nitrogen cycle). Other long-term tests can also be used if  
7 conducted to acceptable standard guidelines (see Section [R.7.11.4](#)).

8 Where adequate long-term data are available, it would generally not be necessary to  
9 conduct further testing on short-term or acute effects.

10 Where long-term toxicity data are not available, all the other data available should be  
11 examined to determine whether the data needs of the chemical safety assessment are  
12 met. The adequacy and relevance of these data are described above. Only where the  
13 data on aquatic effects, and/or short-term toxicity are insufficient to complete the  
14 chemical safety assessment, i.e. risks have been identified based on these screening  
15 data, new long-term testing need to be conducted.

1 **Figure R.7.11–1 Weight-of-Evidence approach**

2

3

1 The flow diagram above outlines a systematic approach how to use all available data in a  
2 *Weight-of-Evidence* decision. It provides a step-wise procedure for the assessment of  
3 different types of information, which might be helpful to come to an overall conclusion.  
4 The scheme proposes a flexible sequence of steps, the order of which depends on the  
5 quality and quantity of data: When for any given substance *in vivo* soil data of adequate  
6 quality are available (step 3) performance of step 2 may not be necessary to derive a  
7 PNEC<sub>soil</sub>. However, it is deemed that even when in-vivo data are available, a *Weight-of-*  
8 *Evidence* assessment with other types of data may be useful to increase the confidence  
9 with the derived PNEC<sub>soil</sub> and reduce the remaining uncertainty.

### 10 **Step 1 – Characterization of the substance**

11 Since there are no current requirements for soil testing to provide hazard data for  
12 classification and labelling (Section [R.7.11.5.1](#)) nor for PBT assessment (Section  
13 [R.7.11.5.2](#)) the need for any effect data on soil organisms should be steered by the need  
14 to develop the chemical safety assessment and in particular by the environmental  
15 exposure, fate and behaviour of the substance. The starting point of any assessment  
16 within the soil area should therefore be to gather key parameters that provide insight to  
17 fate and behaviour of the substance:

18 Physico-chemical properties. Water solubility, K<sub>ow</sub>, K<sub>oc</sub>, Henry's constant etc. will  
19 provide information about the distribution in soil, water and air after deposition in/on  
20 soil.

21 Data on degradation (in soil) will provide information as to whether the substance is  
22 likely to disappear from the soil after deposition, or alternatively remain in the soil or  
23 even accumulate over time which may indicate a potential to cause long-term effects.  
24 Any (major) metabolites being formed should be considered to provide a comprehensive  
25 safety assessment of a substance after deposition on/in soil

### 26 **Step 2 – Identification of possible analogues and alternative data**

27 The effort to identify chemical analogues (read-across) which may take away/modify the  
28 need to search/generate substance-specific data is often the more resource-effective  
29 way to proceed in the assessment. Fate data on an analogue may allow effect-testing of  
30 the substance to become more focused. Effect data on an analogue substance may  
31 potentially be used to waive certain substance-specific testing requirements. It is  
32 however important to understand the limitations of assessing a substance by surrogate  
33 data from analogues, therefore the assessment of remaining uncertainty (see also step  
34 4) is of primary importance here.

35 Where non-testing data (QSARs) are available, these may also be used for a first  
36 screening assessment and to waive certain substance-specific soil-testing requirements  
37 (see Section [R.7.11.5.3](#)).

### 38 **Step 3 – Collating of both testing and non-testing data**

39 Highest priority is given to *in vivo* data which fulfil the data requirements specified in  
40 Annex IX and X. Where such data are available, they are subjected to a careful check of  
41 their quality and relevancy. Good quality data can be used to derive a quantitative  
42 conclusion on the endpoint.

#### 1 **Step 4. *Weight-of-Evidence* assessment**

2 The principle of any comprehensive assessment is to gather all available and potentially  
3 relevant information on a substance, regardless whether these are non-testing (QSARs),  
4 EPM, or soil specific testing (*in vitro* or *in vivo*) data. Any source of information can  
5 potentially be used to focus an assessment or limit uncertainties that remain after  
6 derivation of the endpoint. Even when standard effect data on all 3 taxonomic groups  
7 are available for a substance, further non-standard or non-testing data can be useful in  
8 refining the assessment. Rather than a sequential gathering of data, a single step  
9 collating all the available information is the way into a *Weight-of-Evidence* assessment  
10 for soil organisms

#### 11 Standard studies available (no data-gap)

12 The *Weight-of-Evidence* approach normally starts with an evaluation of the quality of  
13 available data. Standard effects data, using standard species, performed according to  
14 internationally harmonized guidelines (OECD/ISO) and generated under quality criteria  
15 (GLP) clearly represent the highest quality category of data, followed by secondary  
16 sources; non-standard *in vivo* test, *invitro* test and non-testing data. However, even  
17 when standard-tests are available for a substance, further secondary sources of  
18 information (non-standard testing or non-testing) can be used to gain confidence in the  
19 assessment. Supporting evidence from secondary sources reduce the remaining  
20 uncertainty associated with any assessment. Contradictory information between primary  
21 and secondary sources indicate the need to perform a thorough uncertainty analysis.

22 In the event that more than a single standard study is available for the same species  
23 and same endpoint, and there are no obvious quality differences between the studies a  
24 geometric mean value can be derived to be used in assessing the endpoint if the data  
25 are obtained in soils in which the bioavailability of the substance is expected to be  
26 similar. Even in case where data are obtained in soils in which the bioavailability of the  
27 substance is significantly different, a geometric mean can still be used when the data can  
28 be normalized to a given standard condition. If normalization of the data is not possible,  
29 the value obtained in the soil with the highest bioavailability is to be taken to derive the  
30 PNEC.

31 If multiple data are available for the same species but different endpoints, in principle  
32 the most sensitive endpoint is to be taken to derive the PNEC. Prior to this step however,  
33 the relevance of all endpoints to describe the state of the ecosystem is to be considered.

34 If more than a single species was tested in any given organisms group (plant,  
35 invertebrate, micro-organism), allowance should be made for the reduction of the  
36 uncertainty that the availability of such data may provide. Species Sensitivity  
37 Distribution curves (SSD) and Hazard Concentration (HCx) approaches have been used  
38 successfully in Chemical Safety Assessments.

#### 39 Missing standard studies (data-gaps)

40 A full set of standard (GLP) effect test is only infrequently available. There may therefore  
41 be a potential data gaps for substances reaching production volumes > 100 t/y (Annex  
42 IX and X). In this case secondary source data should be used to study whether there is a  
43 need for generating such data to complete the assessment of the end-point, e.g.:

1 If testing data on non-standard species is available, and these studies were carried out  
2 according to a high scientific quality, one may consider to waive the requirement for a  
3 standard test, e.g. a reliable NOEC for a soil-insect other than collembolan may be used  
4 as surrogate data for the group of soil invertebrates, especially when this test indicates  
5 that soil invertebrates are not particularly sensitive to the substance that is assessed.

6 The availability of a study on a standard species which does not completely follow OECD  
7 or ISO guidelines can be used to waive the requirement to run a new study on this  
8 standard species, if the data are scientifically sound, and indicate that this group of  
9 organisms is not critical in the safety assessment.

10 A further use of secondary source effect data is to steer testing requirements, especially  
11 in higher tiers. The identification of a particular sensitive group of organisms in  
12 literature, may lead to the need to extend the scope of higher tier/multi-species studies  
13 to include this group of organisms. For example information from secondary sources may  
14 show that the molecule has specific activity against a certain group of organism (e.g.  
15 plants) and this may allow the assessor to conclude on the end-point based on standard  
16 testing for plants only, and waive the invertebrate and micro-organism testing  
17 requirements in Annex IX and X.

18 If there are several secondary sources data available for the same species, data can be  
19 combined to increase either the statistical power of the conclusion, or the confidence  
20 that the assessor can have in deriving a (screening-) endpoint based on the secondary  
21 data.

22 At the end of any assessment - derivation of the endpoint (PNEC) and assessment of the  
23 remaining uncertainty associated with the assessment/endpoint is required. The TGD  
24 explicitly deals with uncertainties by using assessment factors in the derivation of  
25 PNEC's, but does so merely based on the amount of information available. It does  
26 provide little guidance on how to modify the assessment based on the specific profile of  
27 a substance, nor on the quality of the individual toxicological values (NOEC, ECx) derived  
28 from the studies. The confidence-level associated with any endpoint from an individual  
29 study is largely disregarded. Therefore, in parallel to the quantitative assessment of the  
30 endpoint some estimate on how much confidence the assessor has in this end-point  
31 should ideally be expressed by means of an uncertainty analysis.

#### 32 **R.7.11.6 Integrated testing strategy (ITS) for Effects on Terrestrial** 33 **Organisms.**

34 Fundamentally based on a *Weight-of-Evidence* approach, the integrated testing strategy  
35 (ITS) should be developed with the aim of generating sufficient data for a substance to  
36 support its classification (or exclusion from classification), PBT/vPvB assessment and risk  
37 assessment. For the soil compartment there are currently no criteria for classification  
38 and PBT assessment, therefore the ITS for soil is especially focussed on generating data  
39 for the chemical safety assessment.

##### 40 **R.7.11.6.1 Objective / General principles**

41 The main objective for this testing strategy is to provide guidance on a stepwise  
42 approach to hazard identification with regard to the endpoint. A key principle of the  
43 strategy is that the results of one study are evaluated before another is initiated. The

1 strategy should seek to ensure that the data requirements are met in the most efficient  
2 manner so that animal usage and costs are minimised.

### 3 **R.7.11.6.2 Preliminary considerations**

4 The guidance given in Section [R.7.11.2](#) to [R.7.11.4](#) above will enable the identification of  
5 the data that are needed to meet the requirements of REACH as defined in Annexes VII  
6 to X. Careful consideration of existing environmental data, exposure characteristics and  
7 current risk management procedures is recommended to ascertain whether the  
8 fundamental objectives of the ITS have already been met. Guidance has been provided  
9 on other factors that might mitigate data requirements, e.g. the possession of other  
10 toxic properties, characteristics that make testing technically not possible – for more  
11 guidance, see Section R.5.2.

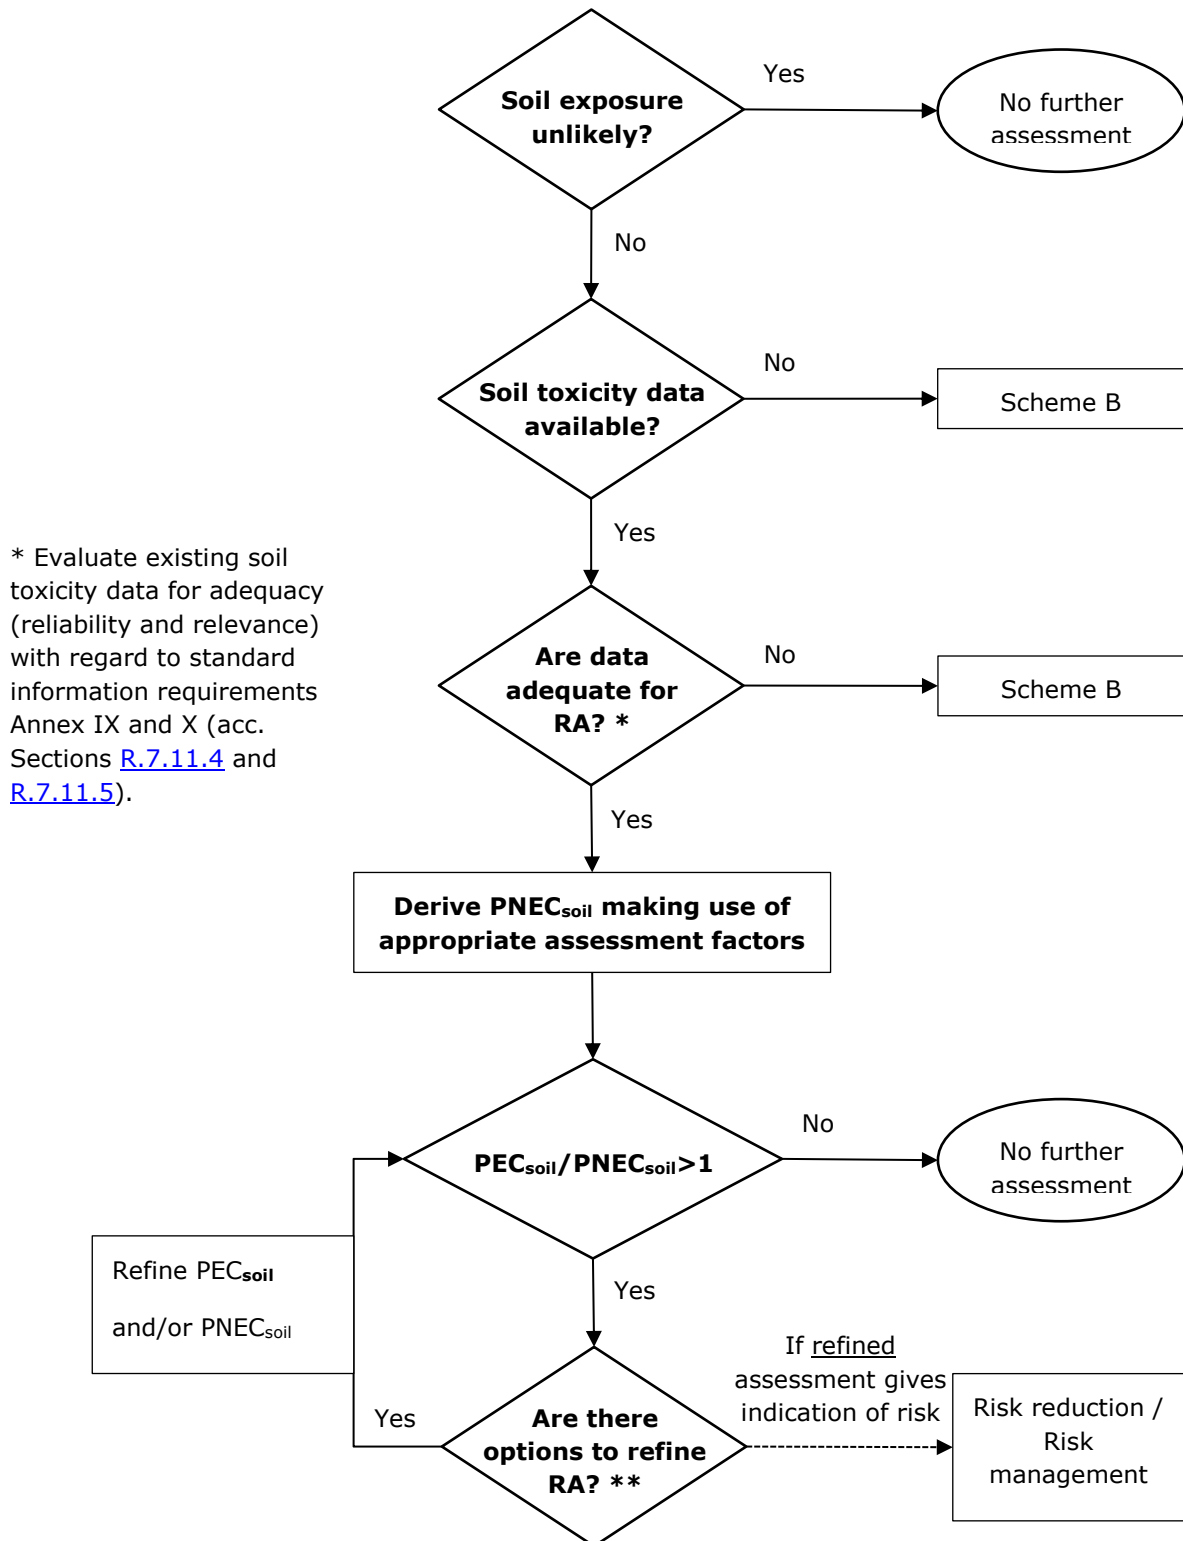

### 12 **R.7.11.6.3 Testing strategy**

13 The general risk assessment approach is given in [Figure R.7.11–2](#) and the ITS in [Figure](#)  
14 [R.7.11–3](#).

15 A testing strategy has been developed for the endpoint to take account of existing  
16 environmental data, exposure characteristics as well as the specific rules for adaptation  
17 from standard information requirements, as described in column 2 of Annexes IX and X,  
18 together with some general rules for adaptation from standard information requirements  
19 in Annex IX.

20

1 **Figure R.7.11–2 Scheme A: General risk assessment scheme**

\* Evaluate existing soil toxicity data for adequacy (reliability and relevance) with regard to standard information requirements Annex IX and X (acc. Sections [R.7.11.4](#) and [R.7.11.5](#)).

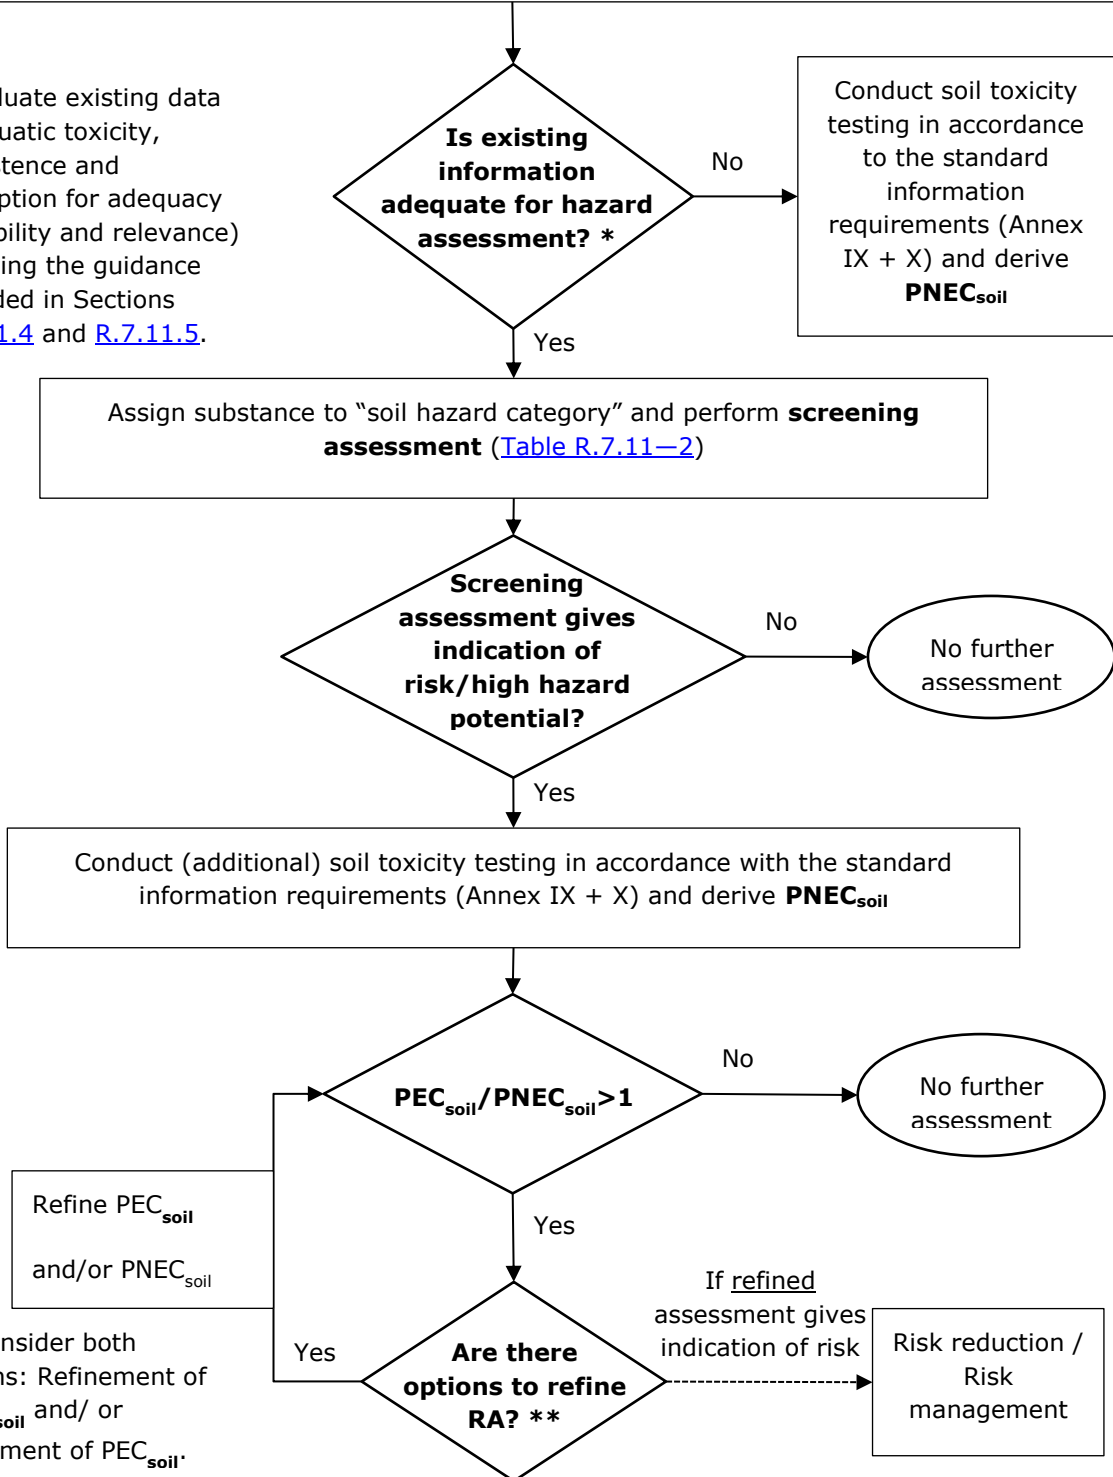

\*\* Consider both options: Refinement of PNEC<sub>soil</sub> and/ or refinement of PEC<sub>soil</sub>.

1 **Figure R.7.11–3 Scheme B: Integrated testing strategy (Annex IX and Annex**  
2 **X substances)**

Gather existing information suitable for a classification of the chemical of interest into a “soil hazard category” (according to [Table R.7.11–2](#)):

1. Aquatic toxicity data (PNEC<sub>aqua</sub>)
2. Persistence (in soil)
3. Adsorption potential (in soil)

\* Evaluate existing data on aquatic toxicity, persistence and adsorption for adequacy (reliability and relevance) following the guidance provided in Sections [R.7.11.4](#) and [R.7.11.5](#).

\*\* Consider both options: Refinement of PNEC<sub>soil</sub> and/or refinement of PEC<sub>soil</sub>.

1 **Table R.7.11—2 Soil hazard categories and screening assessment (for**  
 2 **waiving standard information requirements according Annex IX and X)**

|   | Hazard category 1  | Hazard category 2   | Hazard category 3   | Hazard category 4  |
|---|--|---|---|--|
| Is there indication for <b>high adsorption</b> <sup>15</sup> OR <b>high persistence</b> <sup>16</sup> of the substance in soil? | No   | No  | yes   | Yes  |
| Is there indication that the substance is very toxic <sup>17</sup> to aquatic organisms?  | No   | Yes   | No  | Yes  |
| Approach for screening assessment   | PEC/ PNEC <sub>screen</sub><br>(based on EPM <sup>18</sup> ) | PEC/ PNEC <sub>screen</sub><br>(based on EPM)<br>AND<br>conduct a confirmatory short-term soil toxicity testing<br>(e.g. one limit test with the most sensitive organism group as indicated from aquatic toxicity data) | PEC × 10 / PNEC <sub>screen</sub><br>( based on EPM)<br>AND<br>conduct a confirmatory long-term soil toxicity testing<br>(e.g. one limit test with the most sensitive organism group as indicated from aquatic toxicity data) | Screening assessment based on EPM not recommended, intrinsic properties indicate a high hazard potential to soil organisms |

<sup>15</sup> log K<sub>ow</sub> > 5 or a ionisable substance

<sup>16</sup> DT50 > 180 days (default setting, unless classified as readily biodegradable)

<sup>17</sup> EC/LC50 < 1 mg/L for algae, daphnia or fish

<sup>18</sup> EPM: Equilibrium Partitioning Method

|   | Hazard category 1   | Hazard category 2  | Hazard category 3  | Hazard category 4   |
|---|---|--|--|---|
| Consequences from screening assessment & waiving of standard information requirements   | If $PEC/PNEC_{screen} < 1$ : No toxicity testing for soil organisms need to be done   | If $PEC/PNEC_{screen} < 1$ and no indication of risk from confirmatory short-term soil toxicity testing: No further toxicity testing for soil organisms need to be done  | If $PEC/PNEC_{screen} < 1$ and no indication of risk from confirmatory long-term soil toxicity testing: No further toxicity testing for soil organisms need to be done   | Conduct long-term toxicity tests according to the standard information requirements Annex X (invertebrates and plants), choose lowest value for derivation of $PNEC_{soil}$   |
| toxicity testing with soil organisms and derivation of $PNEC_{soil}$                    | If $PEC/PNEC_{screen} > 1$ : Conduct short-term toxicity tests according to the standard information requirements Annex IX (invertebrates, micro-organisms and plants), choose lowest value for derivation of $PNEC_{soil}$ | If $PEC/PNEC_{screen} > 1$ or indication of risk from confirmatory short-term soil toxicity test: Conduct short-term toxicity tests according to the standard information requirements Annex IX (invertebrates, micro-organisms and plants), choose lowest value for derivation of $PNEC_{soil}$ | If $PEC/PNEC_{screen} > 1$ or indication of risk from confirmatory long-term soil toxicity test: Conduct long-term toxicity tests according to the standard information requirements Annex X (invertebrates and plants), choose lowest value for derivation of $PNEC_{soil}$ |   |
| Options for refinement of $PNEC_{soil}$ (but also consider refinement of $PEC_{soil}$ ) | If $PEC_{soil} / PNEC_{soil} < 1$ : No additional long-term toxicity testing for soil organisms need to be done<br><br>If $PEC_{soil} / PNEC_{soil} > 1$ : Conduct additional or higher tier test on soil organisms         | If $PEC_{soil} / PNEC_{soil} < 1$ : No additional long-term toxicity testing for soil organisms need to be done<br><br>If $PEC_{soil} / PNEC_{soil} > 1$ : Conduct additional or higher Tier test on soil organisms  | If $PEC_{soil} / PNEC_{soil} < 1$ : No additional long-term toxicity testing for soil organisms need to be done<br><br>If $PEC_{soil} / PNEC_{soil} > 1$ : Conduct additional or higher Tier test on soil organisms  | If $PEC_{soil} / PNEC_{soil} < 1$ : No additional long-term toxicity testing for soil organisms need to be done<br><br>If $PEC_{soil} / PNEC_{soil} > 1$ : Conduct additional or higher Tier test on soil organisms |

## 1 **R.7.12 Guidance on Toxicokinetics**

### 2 **R.7.12.1 Upfront information you need to be aware of**

3 The expression of toxicity arising from exposure to a substance is a consequence of a  
4 chain of events that results in the affected tissues of an organism receiving the ultimate  
5 toxicant in amounts that cause an adverse effect. The factors that confer susceptibility to  
6 certain species, and lead to major differences between animals and humans in their  
7 response to such chemical insults is based either on the nature and quantity of the  
8 ultimate toxicant that is presented to the sensitive tissue (toxicokinetics, TK) or in the  
9 sensitivity of those tissues to the ultimate toxicant, i.e. the toxicodynamic (TD)  
10 response. (ECETOC, 2006)

11 There is no specific requirement to generate TK information in REACH. Annex I, Section  
12 1.0.2 states that “the human health hazard assessment shall consider the toxicokinetic  
13 profile (i.e. absorption, metabolism, distribution and elimination) of the substance”.  
14 Furthermore, REACH announces in Annex VIII (Section 8.8.1) that one should perform  
15 “assessment of the toxicokinetic behaviour of the substance to the extent that can be  
16 derived from the relevant available information”.

17 Even though TK is not a toxicological endpoint and is not specifically required by REACH,  
18 the generation of TK information can be encouraged as a means to interpret data, assist  
19 testing strategy and study design, as well as category development, thus helping to  
20 optimise test designs: Prior to any animal study, it is crucial to identify the benefits that  
21 will be gained from conducting such a study. Applicability of physiologically based  
22 pharmacokinetic/toxicokinetic (PBPK/PBTK) models should also be considered to support  
23 or expand understanding of the TK behaviour of a substance (IPCS, 2010). The TK  
24 behaviour derived from available data might make further testing unnecessary in terms  
25 of predictability of other properties. The definition of actual TK studies on a case-by-case  
26 basis might further improve the knowledge about substance properties in terms of  
27 expanding knowledge on properties sufficiently to enable risk assessment. Overall the  
28 formation of data that are unlikely to be used and that constitute an unnecessary effort  
29 of animals, time, and resources shall be avoided using any supporting data to do so.  
30 Moreover, it can provide important information for the design of (subsequent) toxicity  
31 studies, for the application of read-across and building of categories. Taken together,  
32 Along with other approaches, TK can contribute to reduction of animal use under REACH.

33 The aim of this document is to provide a general overview on the main principles of TK  
34 and to give guidance on the generation / use of TK information in the human health risk  
35 assessment of chemicals, and to make use of this information to support testing  
36 strategies to become more intelligent (Integrated Testing Strategy, ITS).

37 The TK phase begins with exposure and results in a certain concentration of the ultimate  
38 toxicant at the target site (tissue dose). This concentration is dependent on the  
39 absorption, distribution, metabolism and excretion (ADME) of the substance (ECETOC,

1 2006). ADME describes the uptake of a substance into the body and its lifecycle within  
2 the body, (including excretion) (compare EU B.36<sup>19</sup>, OECD TG 417):

3 **ABSORPTION:** how, how much, and how fast the substance enters the body;

4 **DISTRIBUTION:** reversible transfer of substances between various parts of the organism,  
5 i.e. body fluids or tissues;

6 **METABOLISM:** the enzymatic or non-enzymatic transformation of the substance of interest  
7 into a structurally different chemical (metabolite);

8 **EXCRETION:** the physical loss of the parent substance and/or its metabolite(s); the  
9 principal routes of excretion are via the urine, bile (faeces), and exhaled air<sup>20</sup>.

10 Metabolism and excretion are the two components of **ELIMINATION**, which describe the  
11 loss of substance by the organism, either by physical departure or by chemical  
12 transformation. For consistency, and unless otherwise specified, metabolism does not  
13 include largely reversible chemical transformations resulting in an observable equilibrium  
14 between two chemical species. This latter phenomenon is termed inter-conversion.

15 The sum of processes following absorption of a chemical into the circulatory systems,  
16 distribution throughout the body, biotransformation, and excretion is called **DISPOSITION**.

#### 17 **R.7.12.1.1 Absorption**

18 The major routes by which toxicants enter the body are via the lungs, the  
19 gastrointestinal tract (both being absorption surfaces by nature), and the skin. To be  
20 absorbed, substances must transverse across biological membranes. Mostly this occurs  
21 by passive diffusion. As biological membranes are built as layers consisting of lipid as  
22 well as aqueous phases a process like this requires a substance to be soluble both in lipid  
23 and water. For chemicals that do not meet these criteria, absorption may occur via  
24 facilitated diffusion, active transport or pinocytosis, processes that are more actively  
25 directed and therefore require energy).

#### 26 **R.7.12.1.2 Distribution**

27 Once the chemical has entered the blood stream, it may exert its toxic action directly in  
28 the blood or in any target tissue or organ to which the circulatory system transports or  
29 distributes it. It is the blood flow through the organ, the ability of the substance to cross  
30 membranes and capillaries, and its relative affinity for the various tissues that determine  
31 the rate of distribution and the target tissues. Regarding the cross-membrane transfer  
32 not only passive mechanisms but also active transport by transport proteins (e.g. p-  
33 glycoprotein) shall be taken into consideration, as this is of particular importance for  
34 crossing the blood-brain-barrier but also elsewhere (e.g. in the intestine).

35 Distribution is in fact a dynamic process involving multiple equilibria: Only the circulatory  
36 system is a distinct, closed *compartment* where chemicals are distributed rapidly.

---

<sup>19</sup> See Test Methods Regulation (Council Regulation (EC) No 440/2008).

<sup>20</sup> Breast milk is a minor but potentially important route of excretion.

1 Distribution to the various tissues and organs is usually delayed. However, often  
2 compounds distribute so rapidly into the highly perfused tissues, such as liver, kidney  
3 and lungs, that kinetics cannot be distinguished from events in the blood; at that point,  
4 such organs are classed as being part of the initial, *central* compartment, and *peripheral*  
5 *compartment* is reserved for slowly equilibrating tissues e.g. muscle, skin and adipose.  
6 There is equilibrium of the free substance between the so-called rapid, or central, and  
7 the slow or peripheral compartment. As the free substance is eliminated, the substance  
8 from the peripheral compartment is slowly released back into the circulation (rapid or  
9 central compartment).

10 This thinking in subdividing the body into different *compartments* is what is made use of  
11 in physiologically based kinetic (PBK) modelling. Based on data of available toxicological  
12 studies, tissue distribution is mathematically calculated using partition coefficients  
13 between blood or plasma and the tissue considered.

#### 14 **R.7.12.1.3 Metabolism or Biotransformation**

15 Biotransformation is one of the main factors, which influence the fate of a chemical in  
16 the body, its toxicity, and its rate and route of elimination. Traditionally  
17 biotransformation is divided into two main phases, phase I and phase II. Phase I, the so-  
18 called functionalisation phase, has a major impact on lipophilic molecules, rendering  
19 them more polar and more readily excretable. In phase II, often referred to as  
20 detoxification, such functionalised moieties are subsequently conjugated with highly  
21 polar molecules before they are excreted. Both phases are catalysed by specific enzymes  
22 which are either membrane-bound (microsomal proteins) or present in the cytosol  
23 (cytosolic or soluble enzymes). Furthermore, it has been suggested that a phase III  
24 relates to the excretion of conjugates and involves ATP<sup>21</sup>-dependent plasma membrane  
25 transporters.

26 Most chemicals are potentially susceptible to biotransformation of some sort, and all cells  
27 and tissues are potentially capable of biotransforming compounds. However, the major  
28 sites of such biotransformation are substrate- and route-dependent; generally, the liver  
29 and the entry portals of the body are the main biotransformation sites to be considered.  
30 Notably, variations occur in the presence of metabolising enzymes in different tissues,  
31 and also between different cells in the same organ. Another aspect is the existence of  
32 marked differences between and within various animal species and humans in the  
33 expression and catalytic activities of many biotransforming enzymes. Any knowledge  
34 concerning metabolic differences may provide crucial insight in characterising the  
35 potential risk of chemicals to humans.

#### 36 **R.7.12.1.4 Excretion**

37 As chemicals are absorbed at different entry portals, they can be excreted via various  
38 routes and mechanisms. The relative importance of the excretion processes depends on  
39 the physical and chemical properties of the compound and its various metabolites.

---

<sup>21</sup> Adenosine-tri-phosphate.

1 Besides passive transportation (diffusion or filtration) there are carrier-mediated  
2 mechanisms to shuttle a substance through a biological membrane. It is well known that  
3 there are a variety of pumps responsible for transportation of specific types of  
4 substances (e.g. sodium, potassium, magnesium, organic acids, and organic bases).  
5 Related compounds may compete for the same transport mechanism. Additional  
6 transport systems, phagocytosis and pinocytosis, can also be of importance (e.g. in the  
7 removal of particulate matter from the alveoli by alveolar phagocytes, and the removal  
8 of some large molecules (Pritchard, 1981) from the body by the reticulo-endothelial  
9 system in the liver and spleen (Klaassen, 1986)).

#### 10 **R.7.12.1.5 Bioavailability, saturation vs. non-linearity & Accumulation**

11 The most critical factor influencing toxicity is the concentration of the ultimate toxicant  
12 at the actual target site (tissue dose). In this context bioavailability is a relevant  
13 parameter for the assessment of the toxicity profile of a test substance. It links dose and  
14 concentration of a substance with the mode of action, which covers the key events  
15 within a complete sequence of events leading to toxicity.

#### 16 **Bioavailability**

17 Bioavailability usually describes the passage of a substance from the site of absorption  
18 into the blood of the general (systemic) circulation, thus meaning systemic bioavailability  
19 (Nordberg *et al.*, 2004). The fact that at least some of the substance considered is  
20 systemically bioavailable is often referred to as systemic exposure.

21 Systemic bioavailability is not necessarily equivalent to the amount of a substance  
22 absorbed, because in many cases parts of that amount may be excreted or metabolised  
23 before reaching the systemic circulation. This may occur, for instance, for substances  
24 metabolised in the gut after oral exposure before any absorption has taken place.  
25 Conversely, substances absorbed from the intestine can be partly eliminated by the liver  
26 at their first passage through that organ (so-called first-pass effect).

#### 27 **Linearity vs. non-linearity & Saturation**

28 When all transfer rates between the different compartments of the body are proportional  
29 to the amounts or concentrations present (this is also called a process of first order), a  
30 process is called linear. This implies that the amounts of a substance cleared and  
31 distributed as well as half-lives are constant and the concentrations are proportional to  
32 the dosing rate (exposure). Such linear kinetics display the respective dose-toxicity-  
33 relationships.

34 Once a kinetic process is saturated (e.g. by high level dosing/exposure) by the fact that  
35 enzymes involved in biotransformation processes, or transporters involved in distribution  
36 or elimination, or binding proteins (i.e. receptors) are inhibited or reaching their  
37 maximum activity, a process might become non-linear. This may result in concentration  
38 or dose-dependency, or time-dependency of some of the kinetic characteristics. In some  
39 cases this can lead to a change in biotransformation products or the metabolic capacity.  
40 It is advised to consider systematically the possible sources for non-linear kinetics,  
41 especially for repeated dose testing.

#### 42 **Accumulation (Kroes *et al.*, 2004)**

1 Everything in a biological system has a biological half-life, that is, a measure of how long  
2 it will stay in that system until it is lost by mainly excretion, degradation, or metabolism.  
3 To put it in different words, the amount of a substance eliminated from the blood in unit  
4 time, is the product of clearance (the volume of blood cleared per unit time) and  
5 concentration (the amount of a compound per unit volume). For first order reactions,  
6 clearance is a constant value that is a characteristic of a substance. If the input of a  
7 substance to an organism is greater than the rate at which the substance is lost, the  
8 organism is said to be accumulating that substance. When the concentration has  
9 increased such that the amount eliminated equals the amount of substance-input there  
10 will be a constant concentration, a steady-state. The extent of accumulation reflects the  
11 relationship between the body-burden compared with the steady-state condition. Species  
12 differences in clearance will determine the difference in steady-state body-burden  
13 between experimental animals and humans.

#### 14 **R.7.12.2 TK in practice – derivation and generation of information**

15 In general, testing a substance for its toxicological profile is performed in laboratory  
16 animals exposed to a range of dosages or concentrations by the most appropriate route  
17 of administration derived from the most likely human exposure scenario. In assessing  
18 gained information in terms of human relevance, the conservative approach of applying  
19 an *assessment factor* (default approach) is used for taking into account uncertainties  
20 over interspecies and intraspecies differences in sensitivity to a specific test substance.

21 In situations, e.g. where humans are demonstrably much less sensitive than the test  
22 species or, indeed, where it is known that the effects seen in the test animal would  
23 under no circumstances be manifested in humans, such conservatism can be considered  
24 inappropriate (ECETOC, 2006). The mode of action (key events in the manifestation of  
25 toxicity) underlying the effect can justify departure from the default approach and enable  
26 a more realistic risk assessment by the arguments even to the point of irrelevance for  
27 the human situation.

28 A tiered approach has been proposed by SANCO (EC, 2007) for the risk assessment of a  
29 substance. In alignment with this, a strategy can be derived on how much effort on TK  
30 evaluation for different levels of importance of a substance is appropriate. Considerations  
31 on the possible activity profile of a substance derived from physico-chemical and other  
32 data, as well as structurally related substances should be taken into account as a  
33 minimum request. This might help in the argumentation on waiving or triggering further  
34 testing and could provide a first impression of the mode of action of a substance.  
35 Subsequent toxicokinetic data needs to be focussed on which studies are needed to  
36 interpret and direct any additional toxicity studies that may be conducted. The  
37 advantage of such effort is that the results enable the refinement of the knowledge of  
38 the activity of a substance by elucidating step by step the mode of action. In this  
39 cascade, the application of assessment factors changes from overall default values to  
40 chemical specific adjustment factors (CSAFs).

#### 41 **R.7.12.2.1 Derivation of TK information taking into account a Basic** 42 **Data Set**

43 The standard information requirements of REACH for substances manufactured or  
44 imported in quantities of  $\geq 1$  ton (see Annex VII of the respective regulation), include  
45 mainly physico-chemical (PC) data, and data like skin irritation/corrosion, eye irritation,

1 skin sensitization, *in vitro* mutagenicity, acute oral toxicity, short-term aquatic toxicity  
2 on invertebrates, growth inhibition of algae. Therefore, these data will be available for  
3 the majority of substances. This data will enable qualitative judgments of the TK  
4 behaviour. However, the physico-chemical characteristics of the substance will change if  
5 the substance undergoes metabolic transformation and the physico-chemical  
6 characteristics of the parent substance may not provide any clues as to the identity,  
7 distribution, retention and elimination of its metabolites. These are important factors to  
8 consider.

## 9 **Absorption**

10 Absorption is a function of the potential for a substance to diffuse across biological  
11 membranes. In addition to molecular weight the most useful parameters providing  
12 information on this potential are the octanol/water partition coefficient (log P) value and  
13 the water solubility. The log P value provides information on the relative solubility of the  
14 substance in water and the hydrophobic solvent octanol (used as a surrogate for lipid)  
15 and is a measure of lipophilicity. Log P values above 0 indicate that the substance is  
16 more soluble in octanol than water i.e. lipophilic and negative values indicate that the  
17 substance is more soluble in water than octanol i.e. hydrophilic. In general, log P values  
18 between -1 and 4 are favourable for absorption. Nevertheless, a substance with such a  
19 log P value can be poorly soluble in lipids and hence not readily absorbed when its water  
20 solubility is very low. It is therefore important to consider both, the water solubility of a  
21 substance and its log P value, when assessing the potential of that substance to be  
22 absorbed.

## 23 **Oral / GI absorption**

24 When assessing the potential of a substance to be absorbed in the gastrointestinal (GI)  
25 tract it should be noted that substances could undergo chemical changes in the GI fluids  
26 as a result of metabolism by GI flora, by enzymes released into the GI tract or by  
27 hydrolysis. These changes will alter the physico-chemical characteristics of the substance  
28 and hence predictions based upon the physico-chemical characteristics of the parent  
29 substance may no longer apply (see [Appendix R.7.12-1](#) for a detailed listing of  
30 *physiological factors*, data on stomach and intestine pH, data on transit time in the  
31 intestine).

32 One consideration that could influence the absorption of ionic substances (i.e. acids and  
33 bases) is the varying pH of the GI tract. It is generally thought that ionized substances  
34 do not readily diffuse across biological membranes. Therefore, when assessing the  
35 potential for an acid or base to be absorbed, knowledge of its pKa (pH at which 50% of  
36 the substance is in ionized and 50% in non-ionised form) is advantageous. Absorption of  
37 acids is favoured at pHs below their pKa whereas absorption of bases is favoured at pHs  
38 above their pKa.

39 Other mechanisms by which substances can be absorbed in the GI tract include the  
40 passage of small water-soluble molecules (molecular weight up to around 200) through  
41 aqueous pores or carriage of such molecules across membranes with the bulk passage of  
42 water (Renwick, 1994). The absorption of highly lipophilic substances (log P of 4 or  
43 above) may be limited by the inability of such substances to dissolve into GI fluids and  
44 hence make contact with the mucosal surface. However, the absorption of such  
45 substances will be enhanced if they undergo micellar solubilisation by bile salts (Aungst

1 and Shen, 1986). Substances absorbed as micelles (aggregate of surfactant molecules,  
2 lowering surface tension) enter the circulation via the lymphatic system, bypassing the  
3 liver. Although particles and large molecules (with molecular weights in the 1000's)  
4 would normally be considered too large to cross biological membranes, small amounts of  
5 such substances may be transported into epithelial cells by pinocytosis or persorption  
6 (passage through gaps in membranes left when the tips of villi are sloughed off) (Aungst  
7 and Shen, 1986). Absorption of surfactants or irritants may be enhanced because of  
8 damage to cell membranes.

9 Absorption can occur at different sites and with different mechanisms along the GI tract.  
10 In the *mouth* absorption is minimal and if at all, occurs by passive diffusion. Therefore,  
11 substances enter directly the systemic circulation, however, some enzymatic degradation  
12 may occur. Like in the mouth, absorption in the *stomach* is minimal and occurs only by  
13 passive diffusion - the acidic environment favours uptake of weak acids. There is a  
14 potential for hydrolysis and, very rarely, metabolism (by endogenous enzymes) prior to  
15 uptake. Once absorbed at this point, substances will go to the liver before entering the  
16 systemic circulation - first pass metabolism may then limit the systemic bioavailability of  
17 the parent compound. The *small intestine* has a very large surface area and the transit  
18 time through this section is the longest, making this the predominant site of absorption  
19 within the GI tract. Most substances will be absorbed by passive diffusion. However,  
20 lipophilic compounds may form micelles and be absorbed into the lymphatic system and  
21 larger molecules/particles may be taken up by pinocytosis. Metabolism prior to  
22 absorption may occur by gut microflora or enzymes in the GI mucosa. Since substances  
23 that enter the blood at this point pass through the liver before entering the systemic  
24 circulation, hepatic first pass metabolism may limit the amount of parent compound that  
25 enters the systemic circulation. In the *large intestine*, absorption occurs mainly by  
26 passive diffusion. But active transport mechanisms for electrolytes are present, too.  
27 Compared to the small intestine, the rate and extent of absorption within the large  
28 intestine is low. Most blood flow from the large intestine passes through the liver first.

29 **Table R.7.12—1 Interpretation of data regarding oral/GI absorption**

| Data source      | What it tells us   |
|------------------|--|
| Structure        | It may be possible to identify ionisable groups within the structure of the molecule. Groups containing oxygen, sulphur or nitrogen atoms e.g. thiol (SH), sulphonate (SO <sub>3</sub> H), hydroxyl (OH), carboxyl (COOH) or amine (NH <sub>2</sub> ) groups are all potentially ionisable.  |
| Molecular Weight | Generally the smaller the molecule the more easily it may be taken up. Molecular weights below 500 are favourable for absorption; molecular weights above 1000 do not favour absorption.   |
| Particle size    | Generally solids have to dissolve before they can be absorbed. It may be possible for particles in the nanometer size range to be taken up by pinocytosis. The absorption of very large particles, several hundreds of micrometers in diameter, that were administered dry (e.g. in the diet) or in a suspension may be reduced because of the time taken for the particle to dissolve. This would be particularly relevant for poorly water-soluble substances. |

| Data source        | What it tells us  |
|--------------------|---|
| Water Solubility   | Water-soluble substances will readily dissolve into the gastrointestinal fluids. Absorption of very hydrophilic substances by passive diffusion may be limited by the rate at which the substance partitions out of the gastrointestinal fluid. However, if the molecular weight is low (less than 200) the substance may pass through aqueous pores or be carried through the epithelial barrier by the bulk passage of water.   |
| Log P              | Moderate log P values (between -1 and 4) are favourable for absorption by passive diffusion. Any lipophilic compound may be taken up by micellar solubilisation but this mechanism may be of particular importance for highly lipophilic compounds (log P >4), particularly those that are poorly soluble in water (1 mg/l or less) that would otherwise be poorly absorbed.  |
| Dosing Vehicle     | If the substance has been dosed using a vehicle, the water solubility of the vehicle and the vehicle/water partition coefficient of the substance may affect the rate of uptake. Compounds delivered in aqueous media are likely absorbed more rapidly than those delivered in oils, and compounds delivered in oils that can be emulsified and digested e.g. corn oil or arachis oil are likely to be absorbed to a greater degree than those delivered in non-digestible mineral oil (liquid petrolatum) (d'Souza, 1990) or in soil, the latter being an important vehicle for children.  |
| Oral toxicity data | If signs of systemic toxicity are present, then absorption has occurred <sup>22</sup> . Also colored urine and/or internal organs can provide evidence that a colored substance has been absorbed. This information will give no indication of the amount of substance that has been absorbed. Also some clinical signs such as hunched posture could be due to discomfort caused by irritation or simply the presence of a large volume of test substance in the stomach and reduced feed intake could be due to an unpalatable test substance. It must therefore be clear that the effects that are being cited as evidence of systemic absorption are genuinely due to absorbed test substance and not to local effects at the site of contact effects.  |
| Hydrolysis Test    | Hydrolysis data are not always available. The hydrolysis test (EU C.7 <sup>23</sup> ; OECD TG 111) conducted for >10 tons substances notified under REACH (Annex VIII) provides information on the half-life of the substance in water at 50°C and pH values of 4.0, 7.0 and 9.0. The test is conducted using a low concentration, 0.01 M or half the concentration of a saturated aqueous solution (whichever is lower). Since the temperature at which this test is conducted is much higher than that in the GI tract, this test will not provide an estimate of the actual hydrolysis half-life of the substance in the GI tract. However, it may give an indication that the parent compound may only be present in the GI tract for a limited period of time. Hence, toxicokinetic predictions based on the characteristics of the parent compound may be of limited relevance. |

<sup>22</sup> Ensure that systemic effects do not occur secondary to local effects!

<sup>23</sup> See Test Methods Regulation (Council Regulation (EC) No 440/2008).

## 1 **Respiratory absorption – Inhalation**

2 For inhaled substances the processes of deposition of the substance on the surface of the  
3 respiratory tract and the actual absorption have to be differentiated. Both processes are  
4 influenced by the physico-chemical characteristics of a chemical.

5 Substances that can be inhaled include gases, vapours, liquid aerosols (both liquid  
6 substances and solid substances in solution) and finely divided powders/dusts.  
7 Substances may be absorbed directly from the respiratory tract or, through the action of  
8 clearance mechanisms, may be transported out of the respiratory tract and swallowed.  
9 This means that absorption from the GI tract will contribute to the total systemic burden  
10 of substances that are inhaled.

11 To be readily soluble in blood, a gas or vapour must be soluble in water and increasing  
12 water solubility would increase the amount absorbed per breath. However, the gas or  
13 vapour must also be sufficiently lipophilic to cross the alveolar and capillary membranes.  
14 Therefore, a moderate log P value (between -1 and 4) would be favourable for  
15 absorption. For vapours, the deposition pattern of readily soluble substances differs from  
16 lipophilic substances in that the hydrophilic are effectively removed from the air in the  
17 upper respiratory tract, whereas the lipophilic reach the deep lung and thus absorption  
18 through the huge gas exchange region may occur. The rate of systemic uptake of very  
19 hydrophilic gases or vapours may be limited by the rate at which they partition out of  
20 the aqueous fluids (mucus) lining the respiratory tract and into the blood. Such  
21 substances may be transported out of the deposition region with the mucus and  
22 swallowed or may pass across the respiratory epithelium via aqueous membrane pores.  
23 Highly reactive gases or vapours can react at the site of contact thereby reducing the  
24 amount available for absorption. Besides the physico-chemical properties of the  
25 compound physical activity (such as exercise, heavy work, etc.) has a great impact on  
26 absorption rate and must also be addressed (Csanady and Filser, 2001).

27 Precise deposition patterns for dusts will depend not only on the particle size of the dust  
28 but also the hygroscopicity, electrostatic properties and shape of the particles and the  
29 respiratory dynamics of the individual. As a rough guide, particles with aerodynamic  
30 diameters below 100 µm have the potential to be inspired. Particles with aerodynamic  
31 diameters below 50 µm may reach the thoracic region and those below 15 µm the  
32 alveolar region of the respiratory tract. These values are lower for experimental animals  
33 with smaller dimensions of the structures of the respiratory tract. Particles with  
34 aerodynamic diameters of above 1-5 µm have the greatest probability of settling in the  
35 nasopharyngeal region whereas particles with aerodynamic diameters below 1-5 µm are  
36 most likely to settle in the tracheo-bronchial or pulmonary regions (Velasquez, 2006).  
37 Thus the quantitative deposition pattern of particles in the respiratory tract varies.  
38 Nonetheless general deposition patterns may be derived (Snipes, 1989). Several models  
39 exist to predict the particle size deposition patterns in the respiratory tract (US EPA,  
40 1994).

41 Generally, liquids, solids in solution and water-soluble dusts would readily  
42 diffuse/dissolve into the mucus lining the respiratory tract. Lipophilic substances (log P  
43 >0) would then have the potential to be absorbed directly across the respiratory tract  
44 epithelium. There is some evidence to suggest that substances with higher log P values  
45 may have a longer half-life within the lungs but this has not been extensively studied

1 (Cuddihy and Yeh, 1988). Very hydrophilic substances might be absorbed through  
 2 aqueous pores (for substances with molecular weights below around 200) or be retained  
 3 in the mucus and transported out of the respiratory tract. For poorly water-soluble dusts,  
 4 the rate at which the particles dissolve into the mucus will limit the amount that can be  
 5 absorbed directly. Poorly water-soluble dusts depositing in the nasopharyngeal region  
 6 could be coughed or sneezed out of the body or swallowed (Schlesinger, 1995). Such  
 7 dusts depositing in the tracheo-bronchial region would mainly be cleared from the lungs  
 8 by the mucocilliary mechanism and swallowed. However a small amount may be taken  
 9 up by phagocytosis and transported to the blood via the lymphatic system. Poorly water-  
 10 soluble dusts depositing in the alveolar region would mainly be engulfed by alveolar  
 11 macrophages. The macrophages will then either translocate particles to the ciliated  
 12 airways or carry particles into the pulmonary interstitium and lymphoid tissues.

13 **Table R.7.12–2 Interpretation of data regarding respiratory absorption**

| Data source              | What it tells us   |
|--------------------------|--|
| Vapour Pressure          | Indicates whether a substance may be available for inhalation as a vapour. As a general guide, highly volatile substances are those with a vapour pressure greater than 25 KPa (or a boiling point below 50°C). Substances with low volatility have a vapour pressure of less than 0.5 KPa (or a boiling point above 150°C)  |
| Particle size            | Indicates the presence of inhalable/respirable particles. In humans, particles with aerodynamic diameters below 100 µm have the potential to be inhaled. Particles with aerodynamic diameters below 50 µm may reach the thoracic region and those below 15 µm the alveolar region of the respiratory tract. These values are lower for experimental animals with smaller dimensions of the structures of the respiratory tract. Thus the quantitative deposition pattern of particles in the respiratory tract varies with the particle size distribution of the inspired aerosol and may further depend on physical and physicochemical properties of the particles (e.g. shape, electrostatic charge). Nonetheless general deposition patterns may be derived (Snipes, 1989; US EPA, 1994) |
| Log P                    | Moderate log P values (between -1 and 4) are favourable for absorption directly across the respiratory tract epithelium by passive diffusion. Any lipophilic compound may be taken up by micellar solubilisation but this mechanism may be of particular importance for highly lipophilic compounds (log P >4), particularly those that are poorly soluble in water (1 mg/l or less) that would otherwise be poorly absorbed.  |
| Water Solubility         | Deposition: Vapours of very hydrophilic substances may be retained within the mucus. Low water solubility, like small particle size enhances penetration to the lower respiratory tract. For absorption of deposited material similar criteria as for GI absorption apply  |
| Inhalation toxicity data | If signs of systemic toxicity are present then absorption has occurred. This is not a quantitative measure of absorption.  |
| Oral toxicity data       | If signs of systemic toxicity are present in an oral toxicity study or there are other data to indicate the potential for absorption following ingestion it is likely the substance will also be absorbed if it is inhaled.  |

|                 |  |
|-----------------|--|
| Hydrolysis Test | Hydrolysis data are not always available. The hydrolysis test (EU C.7 <sup>24</sup> , OECD TG 111) conducted for >10 tons substances notified under REACH (Annex VIII) provides information on the half-life of the substance in water at 50°C and pH values of 4.0, 7.0 and 9.0. The test is conducted using a low concentration, 0.01 M or half the concentration of a saturated aqueous solution (whichever is lower). Since the temperature at which this test is conducted is much higher than that in the respiratory tract, this test will not provide an estimate of the actual hydrolysis half-life of the substance in the respiratory tract. However, it may give an indication that the parent compound may only be present in the respiratory tract for a limited period of time. Hence, toxicokinetic predictions based on the characteristics of the parent compound may be of limited relevance. |
|-----------------|--|

## 1 Dermal absorption

2 The skin is a dynamic, living multilayered biomembrane and as such its permeability  
3 may vary as a result of changes in hydration, temperature, and occlusion. In order to  
4 cross the skin, a compound must first penetrate into the *stratum corneum* (non-viable  
5 layer of corneocytes forming a complex lipid membrane) and may subsequently reach  
6 the viable *epidermis*, the *dermis* and the *vascular network*. The stratum corneum  
7 provides its greatest barrier function against hydrophilic compounds, whereas the viable  
8 epidermis is most resistant to penetration by highly lipophilic compounds (Flynn, 1985).

9 Dermal absorption represents the amount of topically applied test substance that is  
10 found in the epidermis (stratum corneum excluded) and in the dermis, and this quantity  
11 is therefore taken as systemically available. Dermal absorption is influenced by many  
12 factors, e.g. physico-chemical properties of the substance, its vehicle and concentration,  
13 and the exposure pattern (e.g. occlusion of the application site) as well as the skin site  
14 of the body (for review see ECETOC, 1993; Howes *et al.*, 1996; Schaefer and  
15 Redelmaier, 1996). The term *percutaneous penetration* refers to *in vitro* experiments  
16 and represents the amount of topically applied test substance that is found in the  
17 receptor fluid – this quantity is taken as systemically available.

18 Substances that can potentially be taken up across the skin include gases and vapours,  
19 liquids and particulates. A tiered approach for the estimation of skin absorption has been  
20 proposed within a risk assessment framework (EC, 2007): Initially, basic physico-  
21 chemical information should be taken into account, i.e. molecular mass and lipophilicity  
22 (log P). Following, a default value of 100% skin absorption is generally used unless  
23 molecular mass is above 500 and log P is outside the range [-1, 4], in which case a  
24 value of 10%<sup>25</sup> skin absorption is chosen (de Heer *et al.*, 1999). A flow diagram outlining  
25 this tiered approach is presented in [Appendix R.7.12-4](#).

<sup>24</sup> See Test Methods Regulation (Council Regulation (EC) No 440/2008).

<sup>25</sup> The lower limit of 10% was chosen, because there is evidence in the literature that substances with molecular weight and/or log P values at these extremes can to a limited extent cross the skin. If data are available (e.g. data on water solubility, ionogenic state, 'molecular volume', oral absorption and dermal area dose in exposure situations in practice) which indicate the use of an alternative dermal absorption percentage value is appropriate, then this alternative value can be used. Scientific justification for the use of alternative values should be provided.

1 **Table R.7.12–3 Interpretation of data regarding dermal absorption**

| Data source      | What it tells us  |
|------------------|---|
| Physical State   | Liquids and substances in solution are taken up more readily than dry particulates. Dry particulates will have to dissolve into the surface moisture of the skin before uptake can begin. Absorption of volatile liquids across the skin may be limited by the rate at which the liquid evaporates off the skin surface (Pryde and Payne, 1999).  |
| Molecular Weight | Less than 100 favours dermal uptake. Above 500 the molecule may be too large.   |
| Structure        | <p>As a result of binding to skin components the uptake of chemicals with the following groups can be slowed:</p> <p>certain metal ions, particularly Ag<sup>+</sup>, Cd<sup>2+</sup>, Be<sup>2+</sup> and Hg<sup>2+</sup></p> <p>acrylates, quaternary ammonium ions, heterocyclic ammonium ions, sulphonium salts.</p> <p>A slight reduction in the dermal uptake of chemicals belonging to the following substance classes could also be anticipated for the same reason:</p> <p>Quinines, dialkyl sulphides, acid chlorides, halotriazines, dinitro or trinitro benzenes.</p>   |
| Water Solubility | The substance must be sufficiently soluble in water to partition from the stratum corneum into the epidermis. Therefore if the water solubility is below 1 mg/l, dermal uptake is likely to be low. Between 1-100 mg/l absorption is anticipated to be low to moderate and between 100-10,000 mg/l moderate to high. However, if water solubility is above 10,000 mg/l and the log P value below 0 the substance may be too hydrophilic to cross the lipid rich environment of the stratum corneum. Dermal uptake for these substances will be low.   |
| Log P            | <p>For substances with log P values &lt;0, poor lipophilicity will limit penetration into the stratum corneum and hence dermal absorption. Values &lt;-1 suggest that a substance is not likely to be sufficiently lipophilic to cross the stratum corneum, therefore dermal absorption is likely to be low.</p> <p>Log P values between 1 and 4 favour dermal absorption (values between 2 and 3 are optimal) particularly if water solubility is high.</p> <p>Above 4, the rate of penetration may be limited by the rate of transfer between the stratum corneum and the epidermis, but uptake into the stratum corneum will be high.</p> <p>Above 6, the rate of transfer between the stratum corneum and the epidermis will be slow and will limit absorption across the skin. Uptake into the stratum corneum itself may be slow.</p> |

| Data source                   | What it tells us   |
|-------------------------------|--|
| Vapour Pressure               | The rate at which gases and vapours partition from the air into the stratum corneum will be offset by the rate at which evaporation occurs therefore although a substance may readily partition into the stratum corneum, it may be too volatile to penetrate further. This can be the case for substances with vapour pressures above 100-10,000 Pa (ca. 0.76-76 mm Hg) at 25°C, though the extent of uptake would also depend on the degree of occlusion, ambient air currents and the rate at which it is able to transfer across the skin. Vapours of substances with vapour pressures below 100 Pa are likely to be well absorbed and the amount absorbed dermally may be more than 10% of the amount that would be absorbed by inhalation. |
| Surface Tension               | If the surface tension of an aqueous solution is less than 10 mN/m, the substance is a surfactant and this will enhance the potential dermal uptake. Surfactants can also substantially enhance the absorption of other compounds, even in the absence of skin irritant effects.   |
| Skin irritation / Corrosivity | If the substance is a skin irritant or corrosive, damage to the skin surface may enhance penetration.  |
| Dermal toxicity data          | Signs of systemic toxicity indicate that absorption has occurred. However, if steps have not been taken to prevent grooming, the substance may have been ingested and therefore signs of systemic toxicity could be due to oral rather than dermal absorption.   |
| Skin sensitization data       | If the substance has been identified as a skin sensitizer then, provided the challenge application was to intact skin, some uptake must have occurred although it may only have been a small fraction of the applied dose.   |
| Trace elements                | If the substance is a cationic trace element, absorption is likely to be very low (<1%). Stable or radio-isotopes should be used and background levels determined to prevent analytical problems and inaccurate recoveries.  |

1 Even though many factors ([Table R.7.12–3](#)) are linked to the chemical itself, one should  
 2 bear in mind that the final preparation or the conditions of its production or use can  
 3 influence both rate and extent of dermal absorption. These factors should also be taken  
 4 into account in the risk assessment process, including at the stage of estimating dermal  
 5 absorption<sup>26</sup>. Also, the methods described are focused on the extent of absorption, and  
 6 not on its rate (with the exception of *in vitro* studies), which can play a major role in  
 7 determining acute toxicity.

## 8 **Distribution**

9 The concentration of a chemical in blood or plasma (blood level) is dependent on the  
 10 dose, the rates of absorption, distribution and elimination, and on the affinity of the  
 11 tissues for the compound. Tissue affinity is usually described using a parameter known  
 12 as volume of distribution, which is a proportionality factor between the amount of  
 13 compound present in the body and the measured plasma or blood concentration. The

---

<sup>26</sup> In determining the dermal penetration the dosing vehicle seems to be of great importance!

1 larger the volume of distribution is, the lower the blood level will be for a given amount  
2 of compound in the body. A particularly useful volume term is the volume of distribution  
3 at steady-state ( $V_{d_{ss}}$ ). At steady-state, all distribution phenomena are completed, the  
4 various compartments of the body are in equilibrium, and the rate of elimination is  
5 exactly compensated by the rate of absorption. In non steady-state situations, the  
6 distribution volume varies with time except in the simplest case of a single-compartment  
7 model. In theory, steady-state can be physically reached only in the case of a constant  
8 zero-order input rate and stable first-order distribution and elimination rates. However,  
9 many real situations are reasonably close to steady-state, and reasoning at steady-state  
10 is a useful method in kinetics.

11 The rate at which highly water-soluble molecules distribute may be limited by the rate at  
12 which they cross cell membranes and access of such substances to the central nervous  
13 system (CNS) or testes is likely to be restricted by the blood-brain and blood-testes  
14 barriers (Rozman and Klaassen, 1996). It is not clear what barrier properties the  
15 placenta may have. However, species differences in transplacental transfer may occur  
16 due to differing placental structure and also differing metabolic capacity of the placenta  
17 and placental transporters in different species.

18 Although protein binding can limit the amount of a substance available for distribution, it  
19 will generally not be possible to determine from the available data which substances will  
20 bind to proteins and how avidly they will bind. Furthermore, if a substance undergoes  
21 extensive first-pass metabolism, predictions made on the basis of the physico-chemical  
22 characteristics of the parent substance may not be applicable.

1 **Table R.7.12–4 Interpretation of data regarding distribution**

| Data source       | What it tells us   |
|-------------------|--|
| Molecular Weight  | In general, the smaller the molecule, the wider the distribution.  |
| Water Solubility  | Small water-soluble molecules and ions will diffuse through aqueous channels and pores. The rate at which very hydrophilic molecules diffuse across membranes could limit their distribution.  |
| Log P             | If the molecule is lipophilic (log P >0), it is likely to distribute into cells and the intracellular concentration may be higher than extracellular concentration particularly in fatty tissues.  |
| Target Organs     | If the parent compound is the toxicologically active species, it may be possible to draw some conclusions about the distribution of that substance from its target tissues. If the substance is a dye, coloration of internal organs can give evidence of distribution. This will not provide any information on the amount of substance that has distributed to any particular site. Note that anything present in the blood will be accessible to the bone marrow. |
| Signs of toxicity | Clear signs of CNS effects indicate that the substance (and/or its metabolites) has distributed to the CNS. However, not all behavioural changes indicate that the substance has reached the CNS. The behavioural change may be due to discomfort caused by some other effect of the substance.  |

2

3 **Accumulative potential**

4 It is important to consider the potential for a substance to accumulate or to be retained  
 5 within the body, because as they will then gradually build up with successive exposures  
 6 the body burden can be maintained for long periods of time.

7 Lipophilic substances have the potential to accumulate within the body if the dosing  
 8 interval is shorter than 4 times the whole body half-life. Although there is no direct  
 9 correlation between the lipophilicity of a substance and its biological half-life, substances  
 10 with high log P values tend to have longer half-lives unless their large volume of  
 11 distribution is counter-balanced by a high clearance. On this basis, there is the potential  
 12 for highly lipophilic substances (log P >4) to accumulate in individuals that are  
 13 frequently exposed (e.g. daily at work) to that substance. Once exposure stops, the  
 14 concentration within the body will decline at a rate determined by the half-life of the  
 15 substance. Other substances that can accumulate within the body include poorly soluble  
 16 particulates that deposited in the alveolar region of the lungs, substances that bind  
 17 irreversibly to endogenous proteins and certain metals and ions that interact with the  
 18 matrix of the bone (Rozman and Klaassen, 1996).

1 **Table R.7.12—5 Interpretation of data regarding accumulation**

| Site            | Characteristics of substances of concern  |
|-----------------|---|
| Lung            | <p>Poorly water and lipid soluble particles (i.e. log P values around 0 and water solubility around 1 mg/l or less) with aerodynamic diameters of 1 µm or below have the potential to deposit in the alveolar region of the lung. Here particles are likely to undergo phagocytosis by alveolar macrophages. The macrophages will then either translocate particles to the ciliated airways or carry particles into the pulmonary interstitium and lymphoid tissues. Particles can also migrate directly to the pulmonary interstitium and this is likely to occur to the greatest extent where the particle is toxic to alveolar macrophages or inhaled in sufficient quantities to overwhelm the phagocytic capabilities of alveolar macrophages. Within the pulmonary interstitium clearance depends on solubilisation alone, which leads to the possibility of long-term retention (Snipes, 1995).</p>  |
| Adipose tissue  | <p>Lipophilic substances will tend to concentrate in adipose tissue and depending on the conditions of exposure may accumulate. If the interval between exposures is less than 4 times the whole body half-life of the substance then there is the potential for the substance to accumulate. It is generally the case that substances with high log P values have long biological half-lives. On this basis, daily exposure to a substance with a log P value of around 4 or higher could result in a build up of that substance within the body. Substances with log P values of 3 or less would be unlikely to accumulate with the repeated intermittent exposure patterns normally encountered in the workplace but may accumulate if exposures are continuous. Once exposure to the substance stops, the substance will be gradually eliminated at a rate dependent on the half-life of the substance. If fat reserves are mobilized more rapidly than normal, e.g. if an individual or animal is under stress or during lactation there is the potential for large quantities of the parent compound to be released into the blood.</p> |
| Bone            | <p>Certain metals e.g. lead and small ions such as fluoride can interact with ions in the matrix of bone. In doing so they can displace the normal constituents of the bone, leading to retention of the metal or ion.</p>  |
| Stratum corneum | <p>Highly lipophilic substances (log P between 4 and 6) that come into contact with the skin can readily penetrate the lipid rich stratum corneum but are not well absorbed systemically. Although they may persist in the stratum corneum, they will eventually be cleared as the stratum corneum is sloughed off.</p>   |

2

3

## 1 **Metabolism**

2 Differences in the way substances are metabolised by different species and within  
3 different tissues is the main reason for species and route specific toxicity. The liver has  
4 the greatest capacity for metabolism and is commonly causing route specific presystemic  
5 effects (first pass) especially following oral intake. However, route specific toxicity may  
6 result from several phenomena, such as hydrolysis within the GI or respiratory tracts,  
7 also metabolism by GI flora or within the GI tract epithelia (mainly in the small intestine)  
8 (for review see Noonan and Wester, 1989), respiratory tract epithelia (sites include the  
9 nasal cavity, tracheo-bronchial mucosa [Clara cells] and alveoli [type 2 cells]) and skin.

10 It is very difficult to predict the metabolic changes a substance may undergo on the  
11 basis of physico-chemical information alone. Although it is possible to look at the  
12 structure of a molecule and identify potential metabolites, it is by no means certain that  
13 these reactions will occur *in vivo* (e.g. the molecule may not reach the necessary site for  
14 a particular reaction to take place). It is even more difficult to predict the extent to  
15 which it will be metabolised along different pathways and what species differences may  
16 exist. Consequently, experimental data shall help in the assessment of potential  
17 metabolic pathways (see Section [R.7.12.2.2](#)).

## 18 **Excretion**

19 The major routes of excretion for substances from the systemic circulation are the urine  
20 and/or the faeces (via bile and directly from the GI mucosa; see Rozman, 1986).

21 The excretion processes involved in the *kidney* are passive glomerular filtration through  
22 membrane pores and active tubular secretion via carrier processes. Substances that are  
23 excreted in the urine tend to be water-soluble and of low molecular weight (below 300 in  
24 the rat, mostly anionic and cationic compounds) and generally, they are conjugated  
25 metabolites (e.g., glucuronides, sulphates, glycine conjugates) from Phase II  
26 biotransformation. Most of them will have been filtered out of the blood by the kidneys  
27 though a small amount may enter the urine directly by passive diffusion and there is the  
28 potential for re-absorption into the systemic circulation across the tubular epithelium.

29 *Biliary excretion* (Smith, 1973) involves active secretion rather than passive diffusion.  
30 Substances that are excreted in the bile tend to have higher molecular weights or may  
31 be conjugated as glucuronides or glutathione derivatives. In the rat it has been found  
32 that substances with molecular weights below around 300 do not tend to be excreted  
33 into the bile (Renwick, 1994). There are species differences and the exact nature of the  
34 substance also plays a role (Hirom *et al.*, 1972; Hirom *et al.*, 1976; Hughes *et al.*,  
35 1973). The excretion of compounds via bile is highly influenced by hepatic function as  
36 metabolites formed in the liver may be excreted directly into the bile without entering  
37 the bloodstream. Additionally, blood flow as such is a determining factor.

38 Substances in the bile pass through the intestines before they are excreted in the faeces  
39 and as a result may undergo enterohepatic recycling (circulation of bile from the liver,  
40 where it is produced, to the small intestine, where it aids in digestion of fats and other  
41 substances, back to the liver) which will prolong their biological half-life. This is a  
42 particularly problem for conjugated molecules that are hydrolysed by GI bacteria to form  
43 smaller more lipid soluble molecules that can then be reabsorbed from the GI tract.  
44 Those substances less likely to re-circulate are substances having strong polarity and

1 high molecular weight. Other substances excreted in the faeces are those that have  
 2 diffused out of the systemic circulation into the gastrointestinal tract directly, substances  
 3 which have been removed from the gastrointestinal mucosa by efflux mechanisms and  
 4 non-absorbed substances that have been ingested or inhaled and subsequently  
 5 swallowed. However, depending on the metabolic changes that may have occurred, the  
 6 compound that is finally excreted may have few or none of the physico-chemical  
 7 characteristics of the parent compound.

8 **Table R.7.12—6 Interpretation of data regarding excretion**

| Route        | Favourable physico-chemical characteristics   |
|--------------|---|
| Urine        | Characteristics favourable for urinary excretion are low molecular weight (below 300 in the rat), good water solubility, and ionization of the molecule at the pH of urine.   |
| Exhaled Air  | Vapours and gases are likely to be excreted in exhaled air. Also volatile liquids and volatile metabolites may be excreted as vapours in exhaled air.   |
| Bile         | In the rat, molecules that are excreted in the bile are amphipathic (containing both polar and nonpolar regions), hydrophobic/strongly polar and have a high molecular weight. In general, in rats for organic cations with a molecular weight below 300 it is unlikely that more than 5-10% will be excreted in the bile, for organic anions e.g. quaternary ammonium ions this cut off may be lower (Smith, 1973). Substances excreted in bile may potentially undergo enterohepatic circulation. This is particularly a problem for conjugated molecules that are hydrolysed by gastrointestinal bacteria to form smaller more lipid soluble molecules that can then be reabsorbed from the GI tract. Those substances less likely to re-circulate are substances having strong polarity and high molecular weight. Little is known about the determinants of biliary excretion in humans. |
| Breast milk  | Substances present in plasma generally also may be found in breast milk. Lipid soluble substances may be present at higher concentrations in milk than in blood/plasma. Although lactation is minor route of excretion, exposure of neonates via nursing to mother's milk may have toxicological significance for some chemicals.   |
| Saliva/sweat | Non-ionized and lipid soluble molecules may be excreted in the saliva, where they may be swallowed again, or in the sweat.  |
| Hair/nails   | Metal ions may be incorporated into the hair and nails.   |
| Exfoliation  | Highly lipophilic substances that have penetrated the stratum corneum but not penetrated the viable epidermis may be sloughed off with skin cells.  |

### 1 **R.7.12.2.2 Generating and Integrating TK information**

2 *In vivo* studies provide an integrated perspective on the relative importance of different  
3 processes in the intact biological system for comparison with the results of the toxicity  
4 studies. To ensure a valid set of TK data, a TK *in vivo* study has to consist of several  
5 experiments that include blood/plasma-kinetics, mass balances and excretion  
6 experiments as well as tissue distribution experiments. Depending on the problem to be  
7 solved, selected experiments (e.g. plasma-kinetics) may be sufficient to provide needed  
8 data for further assessments (e.g. bioavailability).

9 The high dose level administered in an ADME study should be linked to those that cause  
10 adverse effects in toxicity studies. Ideally there should also be a dose without toxic  
11 effect, which should be in the range of expected human exposure. A comparison  
12 between toxic dose levels and those that are likely to represent human exposure values  
13 may provide valuable information for the interpretation of adverse effects and is  
14 essential for extrapolation and risk assessment.

15 In an *in vivo* study the systemic bioavailability is usually estimated by the comparison of  
16 either dose-corrected amounts excreted, or of dose-corrected areas under the curve  
17 (AUC) of plasma (blood, serum) kinetic profiles, after extra- and intravascular  
18 administration. The systemic bioavailability is the dose-corrected amount excreted or  
19 AUC determined after an extravascular substance administration divided by the dose-  
20 corrected amount excreted or AUC determined after an intravascular substance  
21 application, which corresponds by definition to a bioavailability of 100%. This is only  
22 valid if the kinetics of the compound is linear, i.e. dose-proportional, and relies upon the  
23 assumption that the clearance is constant between experiments. If the kinetics is not  
24 linear, the experimental strategy has to be revised on a case-by-case basis, depending  
25 of the type of non-linearity involved (e.g. saturable protein binding, saturable  
26 metabolism etc.).

27 Generally *in vitro* studies provide data on specific aspects of pharmacokinetics such as  
28 metabolism. A major advantage of *in vitro* studies is that it is possible to carry out  
29 parallel tests on samples from the species used in toxicity tests and samples from  
30 humans, thus facilitating interspecies comparisons (e.g., metabolite profile, metabolic  
31 rate constants). In recent years methods to integrate a number of *in vitro* results into a  
32 prediction of ADME *in vivo* by the use of appropriate PBK models have been developed.  
33 Such methods allow both the prediction of *in vivo* kinetics at early stages of  
34 development, and the progressive integration of all available data into a predictive model  
35 of ADME. The resulting information on ADME can be used both to inform development  
36 decisions and as part of the risk assessment process. The uncertainty associated with  
37 the prediction depends largely on the amount of available data.

### 38 **Test substances and analytical methodology**

39 TK and metabolism studies can be carried out using non-labelled compounds, stable  
40 isotope-labelled compounds, radioactively labelled compounds or using dual (stable and  
41 radio-) labelling. The labels should be placed in metabolically stable positions, the  
42 placing of labels such as <sup>14</sup>C in positions from which they can enter the carbon pool of  
43 the test animal should be avoided. If a metabolic degradation of the test substance may  
44 occur, different labelling positions have to be taken into account to be able to determine  
45 all relevant degradation pathways. The radiolabelled compound must be of high

1 radiochemical purity and of adequate specific activity to ensure sufficient sensitivity in  
2 radio-assay methods.

3 Separation techniques are used in metabolism studies to purify and separate several  
4 radioactive fractions in biota such as urine, plasma, bile and others. These techniques  
5 range from relatively simple approaches such as liquid-liquid extraction and column  
6 chromatography to more sophisticated techniques such as HPLC (high pressure liquid  
7 chromatography). These methods also allow for the establishment of a metabolite  
8 profile. Quantitative analytical methods are required to follow concentrations of parent  
9 compound and metabolites in the body as a function of time. The most common  
10 techniques used are LC/MS (liquid chromatography/ mass spectroscopy) and high  
11 performance LC with UV-detection, or if  $^{14}\text{C}$ -labelled material is used, radioactivity-  
12 detection-HPLC. It is worth mentioning that kinetic parameters generally cannot be  
13 calculated from measurement of total radioactivity to receive an overall kinetic estimate.  
14 Nevertheless, to generate exact values one has to address parent compound and  
15 metabolites separately. An analytical step is required to define the radioactivity as  
16 chemical species. This is usually faster than cold analytical methods. Dual labelling (e.g.  
17  $^{13}\text{C}$  and  $^{14}\text{C}/^{12}\text{C}$ ) is the method of choice for structural elucidation of metabolites (by MS  
18 and NMR [nuclear magnetic resonance] spectroscopy). A cold analytical technique, which  
19 incorporates stable isotope labelling (for GC/MS [gas chromatography/ mass  
20 spectroscopy] or LC/MS), is a useful combination. Unless this latter method has already  
21 been developed for the test compound in various matrices (urine, faeces, blood, fat,  
22 liver, kidney, etc.), the use of radiolabelled compound may be less costly than other  
23 methods.

24 In any TK study, the identity and purity of the chemical used in the test must be  
25 assured. Analytical methods capable of detecting undesirable impurities will be required,  
26 as well as methods to assure that the substance of interest is of uniform potency from  
27 batch to batch. Additional methods will be required to monitor the stability and  
28 uniformity of the form in which the test substance is administered to the organisms used  
29 in the TK studies. Finally, methods suitable to identify and quantify the test substance in  
30 TK studies must be employed.

31 In the context of analytical methods, *accuracy* refers to how closely the average value  
32 reported for the assay of a sample agrees with the actual amount of substance being  
33 assayed in the sample, whereas *precision* refers to the amount of scatter in the  
34 measured values around the average result. If the average assay result does not agree  
35 with the actual amount in the sample, the assay is said to be *biased*, i.e., lacks  
36 specificity; bias can also be due to low recovery.

37 Assay *specificity* is perhaps the most serious problem encountered. Although *blanks*  
38 provide some assurance that no instrument response will be obtained in the absence of  
39 the test chemical, a better approach is to select an instrument or bioassay that responds  
40 to some biological, chemical, or physical property of the test chemical that is not shared  
41 with many other substances.

42 Besides, it is also necessary that the assay method is usable over a sufficiently wide  
43 range of concentrations for the toxic chemical and its metabolites. The lower limit of  
44 reliability for an analytical method has been perceived in different ways; frequently, the  
45 term *sensitivity* has been used to indicate the ability of an analytical method to measure  
46 small amounts of a substance accurately and with requisite precision. It is unlikely that a

1 single analytical method will be of use for all of these purposes. Indeed, it is highly  
2 desirable to use more than one method, at times. If two or more methods yield  
3 essentially the same results, confidence in each method is increased.

#### 4 **Important Methods for Generation of ADME data**

##### 5 Evaluation of absorption

6 Absorption is normally investigated by the determination of the test substance and/or its  
7 metabolites in excreta, exhaled air and carcass (i.e. radioactivity balance). The biological  
8 response between test and reference groups (e.g. oral versus intravenous .) is compared  
9 and the plasma level of the test substance and/or its metabolites is determined.

##### 10 Dermal Absorption

11 Technical guidelines on the conduct of skin absorption studies have been published by  
12 OECD in 2004 (EU B.44<sup>27</sup>, OECD TG 427; EU B.45, OECD TG 428; OECD GD 28).  
13 Advantages of the *in vivo* method (EU B.44, OECD TG 427) are that it uses a  
14 physiologically and metabolically intact system, uses a species common to many toxicity  
15 studies and can be modified for use with other species. The disadvantages are the use of  
16 animals, the need for radiolabelled material to facilitate reliable results, difficulties in  
17 determining the early absorption phase and the differences in permeability of the  
18 preferred species (rat) and human skin. Animal skin is generally more permeable and  
19 therefore may overestimate human percutaneous absorption (US EPA, 1992). Also, the  
20 experimental conditions should be taken into account in interpreting the results. For  
21 instance, dermal absorption studies in fur-bearing animals may not accurately reflect  
22 dermal absorption in human beings.

23 *In vitro* systems allow us to apply to a fixed surface area of the skin an accurate dose of  
24 a test chemical in the form, volume and concentration that are likely to be present  
25 during human exposure. One of the key parameters in the regulatory guidelines in this  
26 field is that sink conditions must always be maintained, which may bias the assay by  
27 build-up of the chemical in the reservoir below the skin<sup>28</sup>. A major issue of concern in the  
28 *in vitro* procedure turned out to be the presence of test substance in the various skin  
29 layers, i.e., absorbed into the skin but not passed into the receptor fluid. It was noted  
30 that it is especially difficult to examine very lipophilic substances *in vitro*, because of  
31 their low solubility in most receptor fluids. By including the amount retained in the skin  
32 *in vitro*, a more acceptable estimation of skin absorption can be obtained. Water-soluble  
33 substances can be tested more accurately *in vitro* because they more readily diffuse into  
34 the receptor fluid (OECD GD 28). At present, provided that skin levels are included as  
35 absorbed, results from *in vitro* methods seem to adequately reflect those from *in vivo*  
36 experiments supporting their use as a replacement test to measure percutaneous  
37 absorption.

---

<sup>27</sup> See Test Methods Regulation (Council Regulation (EC) No 440/2008).

<sup>28</sup> A build up of chemical in the reservoir below the skin is not such a problem if a flow through cell is used for *in vitro* testing.

1 If appropriate dermal penetration data are available for rats *in vivo* and for rat and  
2 human skin *in vitro*, the *in vivo* dermal absorption in rats may be adjusted in light of the  
3 relative absorption through rat and human skin *in vitro*. The latter adjustment may be  
4 done because the permeability of human skin is often lower than that of animal skin  
5 (e.g. Howes *et al.*, 1996). A generally applicable correction factor for extrapolation to  
6 man can, however, not be derived, because the extent of overestimation appears to be  
7 dose, substance, and animal specific (ECETOC, 1993; Bronaugh and Maibach, 1987).

8 *In silico* models might also improve the overall knowledge of crucial properties  
9 significantly. Mathematical skin permeation models are usually based on uptake from  
10 aqueous solution which may not be relevant to the exposure scenario being assessed. In  
11 addition, the use of such models for quantitative risk assessment purposes is often  
12 limited because these models have generally been validated by *in vitro* data ignoring the  
13 fate of the skin residue levels. However, these models may prove useful as a screening  
14 tool or for qualitative comparison of skin permeation potential. On a case-by-case basis,  
15 and if scientifically justified, the use of (quantitative) structure activity relationships may  
16 prove useful, especially within a group of closely related substances.

17 It is notable that a project on the Evaluation and Prediction of Dermal Absorption of  
18 Toxic Chemicals (EDETTOX) was conducted (Williams, 2004). A large critically evaluated  
19 database with *in vivo* and *in vitro* data on dermal absorption/penetration of chemicals  
20 has been established. It is available at <http://edetox.ncl.ac.uk>. Based on this data,  
21 existing QSARs were evaluated (Fitzpatrick *et al.*, 2004). Furthermore new models were  
22 developed: a mechanistically based model, which was used to interpret some of the  
23 newly generated data, a simple membrane model and a diffusion model of percutaneous  
24 absorption kinetics. All these models have mostly been based on and applied to rather  
25 large organic molecules and have thus limited relevance for assessment of inorganic  
26 substances. Furthermore, a guidance document was developed for conduct of *in vitro*  
27 studies of dermal absorption/penetration and can be obtained via  
28 <http://www.ncl.ac.uk/edetox/>. Although mainly based on the experiences gathered with  
29 organic substances, parts of this practical guidance on conduct of such studies are also  
30 applicable to inorganic substances.

### 31 Evaluation of Distribution

32 For determination of the distribution of a substance in the body there are two  
33 approaches available at present for analysis of distribution patterns. Quantitative  
34 information can be obtained firstly, using whole-body autoradiographic techniques and  
35 secondly, by sacrificing animals at different times after exposure and determination of  
36 the concentration and amount of the test substance and/or metabolites in tissues and  
37 organs (EU B.36<sup>29</sup>, OECD TG 417).

### 38 Evaluation of the Accumulative Potential

39 *Bioconcentration* refers to the accumulation of a substance dissolved in water by an  
40 aquatic organism. The static *bioconcentration factor* (BCF) is the ratio of the  
41 concentration of a substance in an organism to the concentration in water once a steady

---

<sup>29</sup> See Test Methods Regulation (Council Regulation (EC) No 440/2008).

1 state has been achieved. Traditionally, bioconcentration potential has been assessed  
2 using laboratory experiments that expose fish to the substance dissolved in water (EU  
3 C.13<sup>29</sup>, OECD TG 305). The resulting fish BCF is widely used as a surrogate measure for  
4 bioaccumulation potential.

5 Another possibility to assess the accumulative potential of a substance is to expose rats  
6 repeatedly to a substance (e.g. 4 week daily administration) and determine the body  
7 burden or the amount in a relevant compartment in a time course.

8 Accumulating substances can also be measured in milk and therefore additionally allow  
9 an estimation of transfer to the breast-fed pup.

#### 10 Evaluation of Metabolism

11 *In vivo* TK studies generally only determine the rates of total metabolic clearance (by  
12 measurement of radiolabelled products in blood/plasma, bile, and excrements) rather  
13 than the contributions of individual tissues. It has to be taken into account that the total  
14 metabolic clearance is the sum of the hepatic and potential extrahepatic metabolism.

15 *In vitro* tests can be performed using isolated enzymes, microsomes and microsomal  
16 fractions, immortalised cell lines, primary cells and organ slices. Most frequently these  
17 materials originate from the liver as this is the most relevant organ for metabolism,  
18 however, in some cases preparation from other organs are used for investigation of  
19 potential organ-specific metabolic pathways.

20 When using metabolically incompetent cells an exogenous metabolic activation system is  
21 usually added in to the cultures. For this purpose the post-mitochondrial 9000x g  
22 supernatant (S9 fraction) of whole liver tissue homogenate containing a high  
23 concentration of metabolising enzymes is most commonly employed - the donor species  
24 needs to be considered in the context of the study. In all cases metabolism may either  
25 be directly assessed by specific identification of the metabolites or by subtractive  
26 calculation of the amount of parent substance lost in the process.

#### 27 Evaluation of Excretion

28 The major routes of excretion are in the urine and/or the faeces (via bile and directly  
29 from the GI mucosa; see Rozman, 1986). For this purpose urine, faeces and expired air  
30 and, in certain circumstances, bile are collected and the amount of test substance and/or  
31 metabolites in these excreta is measured (EU B.36<sup>29</sup>, OECD TG 417).

32 The excretion of chemicals (metabolites) in other biological fluids such as *saliva, milk,*  
33 *tears,* and *sweat* is usually negligible compared with renal or biliary excretion. However,  
34 in special cases these fluids may be important to study either for monitoring purposes,  
35 or in the case of milk allowing an assessment of the exposure of infants.

36 For volatile substances and metabolites exhaled air may be an important route of  
37 elimination. Therefore, exhaled air shall be examined in respective cases.

38

39

40

## 1 ***In silico* methods - Kinetic modelling**

2 *In silico* methods for toxicokinetics, can be defined as mathematical models, which can  
3 be used to understand physiological phenomena of absorption, distribution, metabolism  
4 and elimination of chemicals in the body. These methods gather, for example, QSAR  
5 models, compartmental models, or allometric equations (Ings, 1990; Bachmann, 1996).  
6 Their main advantages compared to *classical (in vitro, in vivo)* methods is that they  
7 estimate the toxicokinetics of a given agent quicker, cheaper and reduced the number of  
8 experimental animals. A detailed discussion of the approaches that integrate information  
9 generated *in silico* and *in vitro* is presented in [Appendix R.7.12-2](#) of this document.

10 When using kinetic models, two opposite situations can be schematically described:

- 11 • either the values of some or all parameters are unknown, and the model is  
12 adjusted (fitted) to data in order to extract from the dataset these parameter  
13 values: this is the fitting situation.
- 14 • or the parameter values are considered as known, and the model is used to  
15 generate simulated datasets: this is the simulation situation.

16 Appropriate algorithms, implemented in validated suitable software, are available to  
17 perform fitting and simulation operations. Both model fitting and simulation operations  
18 have specific technical problems and pitfalls, and must be performed by adequately  
19 trained scientists or scientific teams. Simulation is an extremely useful tool, because it is  
20 the only way to predict situations for which it is not, and often will never be possible to  
21 generate or collect real data. The results of carefully designed simulations, with attached  
22 uncertainty estimations, are then the only available tools for quantitative risk  
23 assessment. The better the model-building steps will have been performed, the better  
24 defined will be the predictions, leading ultimately to better-informed regulatory  
25 decisions.

26 In a risk assessment context, to identify TK relationship as best as possible, TK  
27 information collected from *in vitro* and *in vivo* experiments could be analysed on the  
28 basis of *in silico* models. The purpose of TK *in silico* models is to describe or predict the  
29 concentrations and to define the internal dose of the parent chemical or of its active  
30 metabolite. This is important because internal doses provide a better basis than external  
31 exposure for predicting toxic effects. The prediction of pharmaco- or toxicological effects  
32 from external exposure or from internal dose rests upon *in silico* pharmaco- or  
33 toxicodynamic modelling. The combined used of pharmacokinetic models (describing the  
34 relationships between dose / exposure and concentrations within the body), with  
35 pharmacodynamic models (describing the relationship between concentrations or  
36 concentration-derived internal dose descriptors and effects), is called pharmacokinetic /  
37 pharmacodynamic modelling, or PKPD modelling. The term toxicokinetic / toxicodynamic  
38 modelling, or TKTD, covers the same concept.

39 TK models typically describe the body as a set of compartments through which chemicals  
40 travel or are transformed. They fall into two main classes: *empirical* models and  
41 physiologically-based kinetic models (PBK) (Andersen, 1995; Balant and Gex-Fabry,  
42 1990; Clewell and Andersen, 1996; Gerlowski and Jain, 1983). All these models simplify  
43 the complex physiology by subdividing the body into compartments within which the  
44 toxic agent is assumed to be homogeneously distributed (Gibaldi and Perrier, 1982).

1 Empirical TK models represent the body by one or two (rarely more than three)  
2 compartments not reflecting the anatomy of the species. These models are simple (with  
3 a low number of parameters), allow describing many kinds of kinetics and can be easily  
4 fitted to experimental data.

5 The structure and parameter values of *empirical kinetic models* are essentially  
6 determined by the datasets themselves, whether experimental or observational.  
7 Datasets consist generally in concentration versus time curves in various fluids or  
8 tissues, after dosing or exposure by various routes, at various dose or exposure levels,  
9 in various individuals of various species. Classic kinetic models represent the body by a  
10 small number of compartments (usually 1 or 2 per compound or metabolite, rarely 3,  
11 exceptionally more than 3) where ADME phenomena occur. Phenomena are described  
12 using *virtual* volume terms and transfer rates, which are the parameters of the models.  
13 The function of the volume parameters is to relate the concentrations measured, e.g. in  
14 plasma, to the amounts of xenobiotic present in the body. The volumes described in the  
15 model usually have no physiological counterpart.

16 The structure of the model itself is largely determined by the datasets which they are  
17 intended to describe. This is why these models are often said to be *data-driven*, or *top to*  
18 *bottom*. Compared to physiologically based models, classic kinetic models are usually  
19 better adapted to fitting model to data in order to extract parameter values.

20 A *physiologically based (PBK) model* is an independent structural mathematical model,  
21 comprising the tissues and organs of the body with each perfused by, and connected via,  
22 the blood/lymphatic circulatory system. PBK models comprise four main types of  
23 parameter:

- 24 • Physiological
- 25 • Anatomical
- 26 • Biochemical
- 27 • Physicochemical

28 Physiological and anatomical parameters include tissue masses and blood perfusion  
29 rates, estimates of cardiac output and alveolar ventilation rates. Biochemical parameters  
30 include enzyme metabolic rates and polymorphisms, enzyme synthesis and inactivation  
31 rates, receptor and protein binding constants etc. Physico-chemical parameters refer to  
32 partition coefficients. A partition coefficient is a ratio of the solubility of a chemical in a  
33 biological medium, usually blood-air and tissue-blood. Anatomical and physiological  
34 parameters are readily available and many have been obtained by measurement.  
35 Biochemical and physicochemical parameters are compound specific. When such  
36 parameters (see e.g. Brown *et al.*, 1997; Clewell and Andersen, 1996; Dedrick and  
37 Bischoff, 1980) are measured and used to construct an *a priori* model that qualitatively  
38 describes a dataset, then confidence in such a model should be high. In the absence of  
39 measured data, such as partition coefficients, these may be estimated using tissue-  
40 composition based algorithms (Theil *et al.*, 2003). Metabolic rate constants may be  
41 fitted using a PBK model, although this practice should only be undertaken if there are  
42 no other alternatives. A sensitivity analysis (see below) of these models (Gueorguieva *et*  
43 *al.*, 2006; Nestorov, 1999) may be performed for identifying which parameters are  
44 important within a model. It helps prioritizing and focusing on only those parameters

1 which have a significant impact on the risk assessment process and to identify sensitive  
2 population. A discussion on the applicability of PBK Modelling for the development of  
3 assessment factors in risk assessment is presented in [Appendix R.7.12-3](#) of this  
4 document and in the IPCS project document Characterization and Application of  
5 Physiologically Based Pharmacokinetic Models in Risk Assessment (2010).

6 The potential of PBK models to generate predictions from *in vitro* or *in vivo* information  
7 is one of their attractive features in the risk assessment of chemicals. The degree of later  
8 refinement of the predictions will depend on the particular purpose for which kinetic  
9 information is generated, as well as on the feasibility of generating additional data. When  
10 new information becomes available, the PBK model should be calibrated; Bayesian  
11 techniques, for example, can be easily used for that purpose.

12 PBK models are very useful when the kinetic process of interest cannot be directly  
13 observed and then when extrapolations are needed. Indeed, inter-species, inter-  
14 individual, inter-dose or inter-route extrapolations are more robust when they are based  
15 on PBK rather than on empirical models. The intrinsic capacity for extrapolation makes  
16 PBK models particularly attractive for assessing the risk of chemicals, because it will be  
17 usually impossible to gather kinetic data in all species of interest, and particularly in  
18 man, or by all relevant exposure schemes. More specifically, PBK models also allow to  
19 evaluate TK in reprotoxicity, developmental and multi-generational toxicological studies.  
20 PBK model can be developed to depict internal disposition of chemical during pregnancy  
21 in the mother and the embryo/foetus (Corley *et al.*, 2003; Gargas *et al.*, 2000; Lee *et*  
22 *al.*, 2002; Luecke *et al.*, 1994; Young *et al.*, 2001). Lactation transfer of toxicant from  
23 mother to newborn can also be quantified using PBK models (Byczkowski and Lipscomb,  
24 2001; Faqi *et al.*, 1998; You *et al.*, 1999). The main interests of PBK are also the ability  
25 to check complex hypothesis (such as, for example, the existence of an unknown  
26 metabolism pathway or site) and to give predictions on the internal doses (which is not  
27 always observable in human). Finally, they also allow estimation of kinetic parameter  
28 (e.g. metabolism constant) and dose reconstruction from biomarkers.

29 The rationale for using PBK models in risk assessment is that they provide a  
30 documentable, scientifically defensible means of bridging the gap between animal  
31 bioassays and human risk estimates. In particular, they shift the risk assessment from  
32 the administered dose to a dose more closely associated with the toxic effect by  
33 explicitly describing their relationships as a function of dose, species, route and exposure  
34 scenario. The increased complexity and data demands of PBK models must be counter-  
35 balanced by the increased accuracy, biological plausibility and scientific justifiability of  
36 any risk assessment using them. It follows from this that PBK models are more likely to  
37 be used for chemicals of high concern.

### 38 Sensitivity analysis

39 As biological insight increases, more complex mathematical models of physiological  
40 systems that exhibit more complex non-linear behaviour will appear. Although the  
41 governing equations of these models can usually be solved with relative ease using a  
42 generic numerical technique, often the real strength of the model is not the predictions it  
43 produces but how those predictions were produced. That is, how do the hypotheses, that  
44 fit together to make the model, interact with each other? Which of the assumptions or  
45 mechanisms are most important in determining the output? How sensitive is the model  
46 output to changes in input parameters or model structure? Sensitivity analysis

1 techniques exist that can address these questions by giving a measure of the effects on  
2 model output caused by variation in its inputs. SA can be used to determine:

- 3 • Whether a model emulates the organism being studied,
- 4 • Which parameters require additional research to strengthen knowledge,
- 5 • The influence of structures such as *in vitro* scalings,
- 6 • Physiological characteristics/compound specific parameters that have an  
7 insignificant effect on output and may be eliminated from the model,
- 8 • Feasible combinations of parameters where model variation is greatest,
- 9 • Most appropriate regions within the space of input parameters for use in  
10 parameter optimisation,
- 11 • Whether interaction between parameters occurs, and which of them interact  
12 (Saltelli *et al.*, 2000).

13 Predictions from a complex mathematical model require a detailed sensitivity analysis in  
14 order that the limitations of the predictions provided by model can be assessed. A  
15 thorough understanding the model itself can greatly reduce the efforts in collating  
16 physiological and compound specific data, and lead to more refined and focused  
17 simulations that more accurately predict human variability across a population and  
18 identify groups susceptible to toxic effects of a given compound.

19

## 20 **Importance of Uncertainty and Variability**

21 Uncertainty and variability are inherent to a TK study and affect potentially the  
22 conclusion of the study. It is necessary to minimize uncertainty in order to assess the  
23 variability that may exist between individuals so that there is confidence in the TK  
24 results such that they can be useful for risk analysts and decision-makers.

25 *Variability* typically refers to differences in the physiological characteristics among  
26 individuals (inter-individual variability) or across time within a given individual (intra-  
27 individual variability). It may stem from genetic differences, activity level, lifestyles,  
28 physiological status, age, sex *etc.* Variability is inherent in animal and human  
29 populations. It can be observed and registered as information about the population, but  
30 it cannot be reduced. An important feature of variability is that it does not tend to  
31 decrease when larger samples of a population are examined.

32 Variability in the population should then be taken into account in TK studies. Regarding  
33 PBK models, it may be introduced by the use of probability distributions for parameters  
34 representing the distribution of physiological characteristics in the population. The

1 propagation of these variability to model predictions may be evaluated using Monte Carlo  
2 simulations methods.<sup>30</sup>

3 *Uncertainty* can be defined as the inability to make precise and unbiased statements. It  
4 is essentially due to a lack of knowledge. Uncertainty in the information may decrease  
5 with the size of the sample studied. It can be theoretically, eliminated and at least  
6 reduced by further optimised experiments or by a better understanding of the process  
7 under study.

8 Uncertainty may be related to:

9 *The experimental nature of the data.* Indeed, uncertainty comes from errors in  
10 experimental data. Experimental data are typically known with finite precision dependent  
11 of the apparatus used. However such uncertainties may be easily assessed with quality  
12 measurement data. They can be modelled with probability distributions (e.g., the  
13 measured quantity is distributed normally with mean the actual quantity and a given  
14 standard deviation). Uncertainty may also be generated by the data gathering process  
15 and errors made at this stage (reading errors, systematic measurement errors, etc).

16 *The modelling procedure.* Uncertainty is most of the time inescapable due to the  
17 complexity and unknown nature of the phenomena involved (model specification). The  
18 source of uncertainty in the model structure (and more particularly in PBK models) is  
19 primarily a lack of theoretical knowledge to correctly describe the phenomenon of  
20 interest on all scales. In this case, the world is not fully understood and therefore not  
21 modelled exactly. Summing up, in a model, a massive amount of information can in itself  
22 be a technical challenge. An organism may be viewed as an integrated system, whose  
23 components correlations are both strong and multiple (e.g., a large liver volume might  
24 be expected to be associated with a large blood flow). Given the complexity of an  
25 organism, it is not feasible to integrate all the interactions between its components  
26 (most of them are not even fully known and quantified) in the development of a model.  
27 Therefore modellers have to simplify reality. Such assumptions will however introduce  
28 uncertainty. A general statistical approach to quantify model uncertainty is first to  
29 evaluate the accuracy of the model when predicting some datasets. Models based on  
30 different assumptions may be tested and statistical criteria (such as the Akaike  
31 criterion<sup>31</sup>) may be used to discriminate between models

32 *The high inherent variability of biological systems.* The variability itself is a source of  
33 uncertainty. In some cases, it is possible to fully know variability, for example by  
34 exhaustive enumeration, with no uncertainty attached. However, variability may be a  
35 source of uncertainty in predictions if it is not fully understood and ascribed to  
36 randomness.

---

<sup>30</sup> These methods consist of specifying a probability distribution for each model parameter; sampling randomly each model parameter from its specified distribution; running the model using the sampled parameter values, and computing various model predictions of interest. Instead of specifying independent distributions for parameters, a joint probability distribution may be assigned to a group of parameters to describe their correlation.

<sup>31</sup> measure of the logarithm of the likelihood.

1 **R.7.12.2.3 Include human data when available to refine the**  
2 **assessment**

3 Human biological monitoring and biological marker measurement studies provide  
4 dosimetric means for establishing aggregate and/or cumulative absorbed doses of  
5 chemicals following specific situations or exposure scenarios or for establishing baseline,  
6 population-based background levels (Woollen, 1993). The results from these studies,  
7 e.g., temporal situational biological monitoring, provide a realistic description of human  
8 exposure.

9 Biomonitoring, the routine analysis of human tissues or excreta for direct or indirect  
10 evidence of human exposures to substances, can provide unique insights into the  
11 relationship between dose and putative toxicity thresholds established in experimental  
12 animals, usually rats. Pioneering research by Elkins *et al.* (1954) on the relationship  
13 between concentrations of chemicals in the workplace and their concentrations in body  
14 fluids helped to establish the Biological Exposure Index (ACGIH, 2002). Urine is the most  
15 frequently used biological specimen, due to its non-invasive nature and ease of collection  
16 and its importance as a route of excretion for most analytes. The analyte to be  
17 monitored should be selected depending on the metabolism of the compound, the  
18 biological relevance, and feasibility considerations, in order to maximise the relevance of  
19 the information obtained.

20 **R.7.12.2.4 Illustration of the benefit of using TK information**

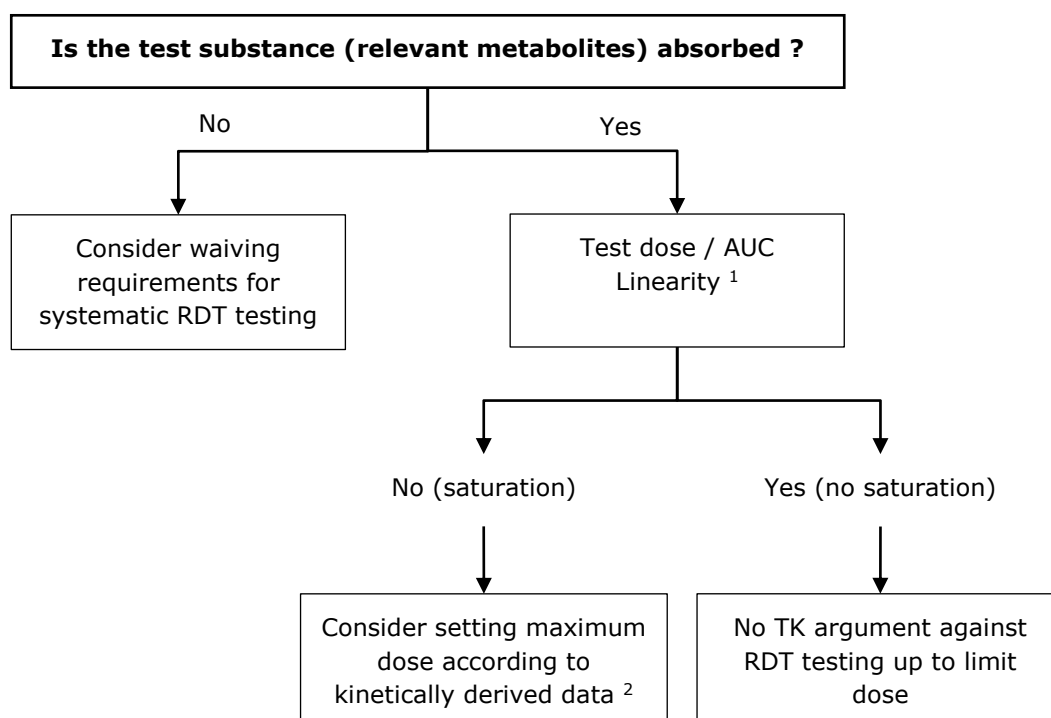

21 The understanding of the mode of action of a substance or at least the estimation  
22 through a category of substances with a similar structure and action supports  
23 argumentation on specific modulation of testing schemes (even waiving) and the overall  
24 interpretation of the biological activity of a substance. The following diagrams shall  
25 illustrate the way of thinking that can be applied regarding making use of TK information  
26 when this is available. It should be acknowledged that just in very rare cases a *yes-no*  
27 answer could be applied. Often a complex pattern of different information creates  
28 specific situations that deviate from the simplified standard procedures given below. The  
29 answer *no* can be understood in regard to *no significant* effect based on substance  
30 dependent expert judgment and detection limits of sensitive test methods (compare  
31 REACH Annex VIII, Section 8.7). Therefore, experts need to be consulted for use of TK  
32 data for designing tests individually, interpretation of results for elucidating the mode of  
33 action or in a grouping or read-across approach and also regarding the use of  
34 computational PBK model systems.

35 **Use of TK information to support Dose Setting Decisions for Repeated**  
36 **Dose Studies**

37 TK data, especially information on absorption, metabolism and elimination, are highly  
38 useful in the process of the design of repeated dose toxicity (RDT) studies. Repeated  
39 dose toxicity studies should be performed according to the respective OECD or EU  
40 guidelines. The highest dose level in such studies should be chosen with the aim to  
41 induce toxicity but not death or severe suffering in the test animals. For doing so, the  
42 OECD or EU guidelines suggest to test up to a standardised limit dose level called  
43 maximum tolerated dose (MTD). It is convenient to remember that such doses may, in  
44 certain cases, cause saturation of metabolism and, therefore, the obtained results need

1 to be carefully evaluated when eventually assessing the risk posed by exposure at levels  
2 where a substance can be readily metabolised and cleared from the body.  
3 Consequently, when designing repeated dose toxicity studies, it is convenient to consider  
4 selecting appropriate dose levels on the basis of results from metabolic and toxicokinetic  
5 investigation. [Figure R.7.12–1](#) illustrates how TK data could assist in dose setting  
6 decisions for repeated dose toxicity studies.

7 **Figure R.7.12–1 Use of TK data in the design of RDT studies**

<sup>1</sup> In the dose-range under consideration for RDT testing

<sup>2</sup> Meaning that the highest dose-level should not exceed into the range of non-linear kinetics.

8

9 The question which needs to be addressed initially is whether the substance is absorbed.  
10 If it can be demonstrated that a substance is not absorbed, it cannot induce direct  
11 systemic effects. In such a case, from the kinetic point of view, there is no need for  
12 further repeated dose testing<sup>32</sup>. If the substance is absorbed the question arises whether  
13 there is a linear relationship between the administered dose and the AUC in the blood. If  
14 this is the case and the substance is not metabolised, then there is no kinetic argument  
15 against testing at the standardised MTD suggested by OECD or EU guidelines.

16 Often the dose/AUC relationship deviates from linearity above a certain dose. This is  
17 illustrated in [Figure R.7.12–2](#). In both cases described the dose level corresponding to  
18 the inflexion point can be regarded as the kinetically derived maximally tolerated dose  
19 (MTD) If information in this regard is available, it might be considered setting the  
20 highest dose level for repeated doses studies according to the kinetically derived MTD.

---

<sup>32</sup> Secondary effects misinterpreted, as primary toxic effects need to be excluded.

1 **Figure R.7.12—2 Departure from linearity at certain doses**

2 In example 1 the AUC does not increase beyond a certain dose level. This is the case  
 3 when absorption becomes saturated above a certain dose level. The dose/AUC  
 4 relationship presented in example 2 can be obtained when elimination or metabolism  
 5 becomes saturated above a certain dose level, resulting in an over proportional increase  
 6 in the AUC beyond this dose.

7  
 8 **Use of kinetic information in the design and validation of categories**

9 Information on kinetics *in vivo* will assist the design of categories. Candidate category  
 10 substances can be identified, with which to perform *in vitro* or *in vivo* tests, thus making  
 11 extrapolation of toxicological findings between substances more relevant.

12 Where there is uncertainty or contradictory information within a category, the category  
 13 or membership of a certain substance to a category can be verified using kinetics  
 14 information.

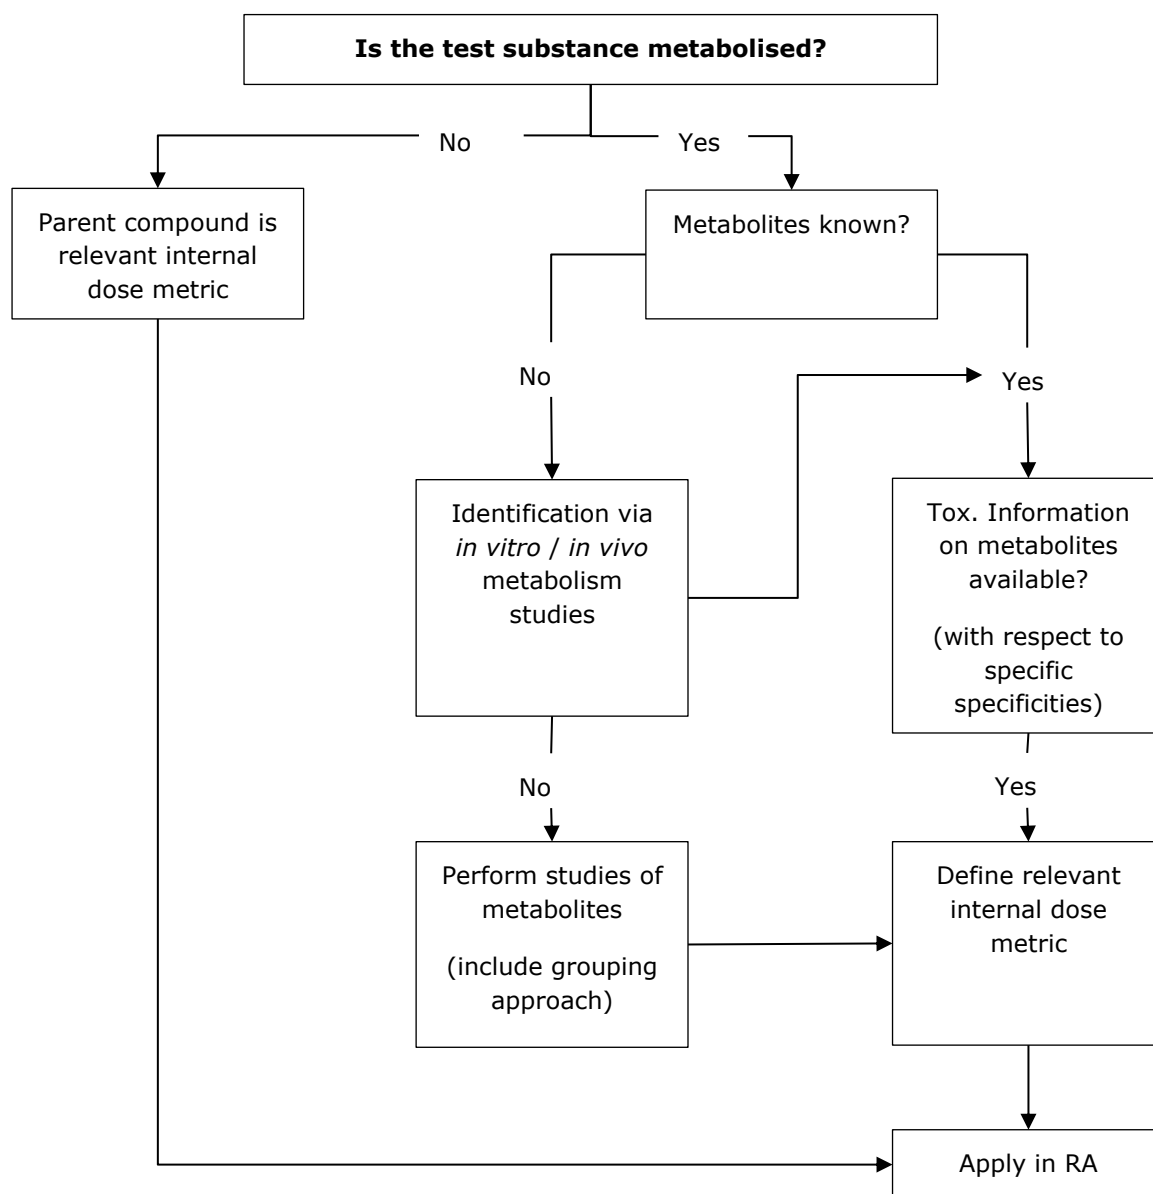

15 **Metabolism Studies as basis for Internal Dose considerations**

16 Biotransformation of a substance produces metabolites that may have different  
 17 toxicological properties than the substrate from which they are formed. Although  
 18 metabolism is generally referred to a detoxification purpose, there are also many  
 19 examples for which metabolites have a higher intrinsic toxicity than the parent  
 20 compound itself (metabolic activation). Therefore, the knowledge if the test substance is  
 21 metabolised and to which metabolites is necessary to enable the assessment of the  
 22 results from toxicity studies in respect to waiving and grouping approaches as well as to  
 23 define an internal dose (see [Figure R.7.12—2](#)).

24 If the test substance is not metabolised, the parent compound is the relevant marker for  
 25 the measurement and the definition of the internal dose. If the test substance is  
 26 metabolised, the knowledge which metabolites are formed is essential for any further  
 27 step in an assessment. When this information is not available, it can be investigated by  
 28 appropriate *in vitro* and/or *in vivo* metabolism studies (see Section [R.7.12.2.1](#)). In  
 29 special cases metabolites may show a high degree of isomeric specificity and this should  
 30 be born in mind in the design and interpretation of mixtures of isomers, including  
 31 racemates. If the metabolites are known and if toxicity studies are available for these  
 32 metabolites, risk assessment may be carried out based on these data and an assessment

1 on the basis of the definition of the internal dose can be made. If the toxicity profile for  
2 the metabolites is unknown, studies that address the toxicity of these metabolites may  
3 be performed under special considerations of potential group approaches (especially if a  
4 chemical substance is the metabolite of different compounds, e.g. like a carboxylic acid  
5 as a metabolite of different esters).

6 **Figure R.7.12–3 Use of increasing knowledge on substance metabolism**

7

8

9

1 TK information can be very helpful in bridging various gaps as encountered in the whole  
2 risk assessment, from toxicity study design and biomonitoring<sup>33</sup> setup to the derivation  
3 of the DNEL (Derived No-Effect Level) and various extrapolations as usually needed  
4 (cross-dose, cross-species including man, cross-exposure regimens, cross-routes, and  
5 cross-substances). The internal dose is the central output parameter of TK studies and  
6 therefore the *external exposure – internal dose – concept* is broadly applicable in the  
7 various extrapolations mentioned (see also Section [R.7.12.2.4](#)). In addition, under  
8 REACH, derivation of DNELs is obligatory. If, for that purpose, route-to-route  
9 extrapolation is necessary and in case assessment of combined exposure (via different  
10 routes) is needed, for systemic effects, internal exposure may have to be estimated.

11 Exposure should normally be understood as external exposure which can be defined as  
12 the amount of substance ingested, the total amount in contact with the skin or either the  
13 amount inhaled or the concentration of the substance in the atmosphere in combination  
14 with the exposure duration, as appropriate. In cases where a comparison needs to be  
15 made with systemic effects data (e.g. when inhalation or dermal toxicity values are  
16 lacking or when exposures due to more than one route need to be combined) the total  
17 body burden has to be estimated and expressed as an internal dose.

18 Determination of the level of systemic exposure is considered synonymous to  
19 determination of bioavailability of a substance to the general circulation. Depending on  
20 the problem considered and other concomitant information such as exposure scenarios,  
21 this could be expressed as a fraction bioavailable (F), a mass bioavailable, a  
22 concentration profile, an average concentration, or an AUC. It should be emphasised that  
23 it is usually not possible to show that the amount of a substance bioavailable is zero,  
24 apart from favourable cases by dermal route, considering only intact skin. This should be  
25 assessed in terms of thresholds, the objective being to establish whether or not the  
26 bioavailability of a substance is predicted to be below a certain threshold. The degree of  
27 certainty of the prediction will depend on each case, important factors being the  
28 accuracy and reliability of the *in vivo*, *in vitro* or *in silico* model used, the performance of  
29 the methods used to assay the substance or its metabolites, the estimated variability in  
30 the target population etc.

31 Tissue distribution characteristics of a compound can be an important determinant of its  
32 potential to cause toxicity in specific tissues. In addition, tissue distribution may be an  
33 important determinant of the ability of a compound to accumulate upon repeated  
34 exposure, although this is substantially modified by the rate at which the compound is  
35 cleared. Correlation of tissue distribution with target tissues in toxicity studies should be  
36 accomplished while substantial amounts of the chemical remain present in the body, for  
37 example, at one or more times around the peak blood concentration following oral  
38 absorption. Such data should quantify parent compound and metabolites, to the extent  
39 feasible. If the metabolites are unknown or difficult to quantify, subtracting parent

---

<sup>33</sup> Biological monitoring information should be seen as equivalent (i.e. as having neither greater nor lesser importance) to other forms of exposure data. It should also be remembered that biological monitoring results reflect an individual's total exposure to a substance from any relevant route, i.e. from consumer products, and/or from the environment and not just occupational exposure. Data from controlled human exposure studies are even more unlikely available. This is due to the practical and ethical considerations involved in deliberate exposure of individuals.

1 compound from total radioactivity will provide an estimate of the behaviour of the total  
2 metabolites formed.

### 3 **Extrapolation**

4 For ethical reasons, data allowing estimating model parameters are poor, sparse, and do  
5 not often concern human populations; recourse to extrapolation is then needed. TK data  
6 are mostly gathered for few concentrations (usually less than 5 different concentrations)  
7 and limited number of different exposure times. However, risk evaluation should also  
8 status on different doses (exposure concentrations and times). Inter-dose/inter-  
9 exposure time extrapolation is a common way to satisfy this request - mathematical  
10 methods (e.g. linear regression) are used for this purpose. The non-linear kinetic  
11 behaviour of chemicals in a biological organism is the result of a number of mechanisms  
12 e.g., saturable metabolism, enzyme induction, enzyme inactivation and depletion of  
13 glutathione and other cofactor reserves. High-dose-low-dose extrapolation of tissue dose  
14 is accomplished with PBK modelling by accounting for such mechanisms (Clewell and  
15 Andersen, 1996).

16 In the rare case where data on human volunteers are available, they only concern a very  
17 limited number of subjects. Extrapolation to other body and to the global population  
18 should be done (inter-individual extrapolation). The problem of sensitive populations also  
19 raises and TK study should status on other gender, age or ethnic groups, for example.  
20 As it is practically nearly impossible to control internal dose in humans, alternative  
21 animal study is often proposed. Since risk assessment aims at protecting human  
22 population, inter-species extrapolation (Davidson *et al.*, 1986; Watanabe and Bois,  
23 1996) should be done. For practical reasons, the administration route in experimental  
24 study can be different from the most likely exposure route. Risk assessment implies then  
25 to conclude on another route than the one experimentally studied. Inter-route  
26 extrapolation should then be performed.

27 Default values have been derived to match the extrapolation idea in a general way. The  
28 incorporation of quantitative data on interspecies differences or human variability in TK  
29 and TD into dose/concentration-response dose assessment through the development of  
30 chemical specific adjustment factors (CSAFs) might improve risk assessment of single  
31 substances. Currently, relevant data for consideration are often restricted to the  
32 component of uncertainty related to interspecies differences in TK. While there are  
33 commonly fewer data at the present time to address interspecies differences in TD,  
34 inter-individual variability in TK and TD, it is anticipated that the availability of such  
35 information will increase with a better common understanding of its appropriate nature  
36 (IPCS, 2001). The type of TK information that could be used includes the rate and extent  
37 of absorption, the extent of systemic availability, the rate and extent of presystemic  
38 (first-pass) and systemic metabolism, the extent of enterohepatic recirculation,  
39 information on the formation of reactive metabolites and possible species differences and  
40 knowledge of the half-life and potential for accumulation under repeated exposure.

41 The need for these extrapolations can lead one to prefer physiological TK models to  
42 empirical models (Davidson *et al.*, 1986; Watanabe and Bois, 1996; Young *et al.*, 2001).  
43 Indeed, PBK models facilitate the required extrapolations (inter-species, inter-subject  
44 etc). By changing anatomical parameters (such as organ volumes or blood flows), a PBK  
45 model can be transposed from rat to human, for example.

1 Interspecies extrapolation

2 The use of animal data for toxicological risk assessment arises the question of how to  
3 extrapolate experimentally observed kinetics to human subjects or populations - the  
4 ability to compare data from animals with those from humans will enable defining  
5 chemical-specific interspecies extrapolation factors to replace the default values. One  
6 possibility to do so is the calculation of allometric factors by extrapolation based on  
7 different body sizes. The most complex procedure for inter-species extrapolation is the  
8 collection of different data and use these in a PBK modelling.

9 Allometric scaling is a commonly employed extrapolation approach. It is based on the  
10 principle that biological diversity is largely explained by body size (Schneider *et al.*,  
11 2004). Allometric scaling captures the correlations of physiological parameters or TK with  
12 body size. More precisely, allometric equations relate the quantity of interest (e.g., a  
13 tissue dose) to a power function of body mass, fitted across species:

14 
$$Y = a BM^b$$

15 where  $Y$  is the quantity of interest,  $a$  is a species-independent scaling coefficient<sup>34</sup>,  $BM$  is  
16 body mass and  $b$  is the allometric exponent. Values of  $b$  depend upon whether the  
17 quantity of interest scales approximately with body mass ( $b=1$ ), metabolic rate<sup>35</sup>  
18 ( $b=0.75$ ), or body surface area ( $b=0.67$ <sup>36</sup>) (Davidson *et al.*, 1986; Fiserova-Bergerova  
19 and Hugues, 1983; West *et al.*, 1997). As it is easy to apply, the allometric scaling is  
20 probably the most convenient approach to interspecies extrapolation. However, it is very  
21 approximate and may not hold for the chemical of interest. As such it can be conceived  
22 only as default approach to be used only in the absence of specific data in the species of  
23 interest.

24 For a chemical that demonstrates significant interspecies variation in toxicity in animal  
25 experiments, the most susceptible species is generally used as the reference for this  
26 extrapolation. Uncertainty factors up to 1000 or more have been applied in recognition  
27 of the uncertainty involved. Whereas a metabolic rate constant estimated in this way  
28 may be used in a PBK model, it is preferable, where possible, to determine such  
29 parameters *in vitro* using tissue subcellular fractions or estimate them by fitting a PBK  
30 model to an appropriate dataset.

31 Consequently, to better estimate tissue exposure across species, PBK models may be  
32 used for the considered toxicant (Watanabe and Bois, 1996). These models account for  
33 transport mechanisms and metabolism within the body. These processes are then  
34 modelled by the same equation set for all species considered. Differences between  
35 species are assumed to be due to different (physiological, chemical, and metabolic)  
36 parameter values. Extrapolation of PBK models then relies on replacing the model  
37 parameter values of one species with the parameter values of the species of interest. For

---

<sup>34</sup> Fits single data points together to form an appropriate curve.

<sup>35</sup> In this context not metabolism of compounds! The factor adapts different levels of oxygen consumption.

<sup>36</sup> This scaling factor is generally justified on the basis of the studies by Freireich *et al* (1966), who examined the interspecies differences in toxicity of a variety of antineoplastic drugs.

1 physiological parameters, numerous references (Arms and Travis, 1988; Brown *et al.*,  
2 1997; ICRP, 2002) give standard parameter values for many species. Chemical  
3 (partitioning coefficient) and metabolic parameter values are usually less easily found.  
4 When parameter values of PBK model are not known for the considered species,  
5 recourse to *in vitro* data, Quantitative Structure-Property Relationships (QSPR)  
6 predictions or allometric scaling of those parameters is still possible. To take into account  
7 population variability in the extrapolation process, probability distributions of parameters  
8 may be used rather than single parameter values. PBK models can be particularly useful  
9 where data are being extrapolated to population subgroups for which the little  
10 information is available e.g. on pregnant women or infants (Luecke *et al.*, 1994; Young  
11 *et al.*, 2001).

#### 12 Inter-route Extrapolation

13 Route-to-route extrapolation is defined as the prediction of the total amount of a  
14 substance administered by one route that would produce the same systemic toxic  
15 response as that obtained for a given amount of a substance administered by another  
16 route.

17 In general, route-to-route extrapolation is considered to be a poor substitute for toxicity  
18 data obtained using the appropriate route of exposure. Uncertainties in extrapolation  
19 increase when it becomes necessary to perform a risk assessment with toxicity data  
20 obtained by an administration route which does not correspond to the human route of  
21 exposure. Insight into the reliability of the current methodologies for route-to-route  
22 extrapolation has not been obtained yet (Wilschut *et al.*, 1998).

23 When route-to-route extrapolation is to be used, the following aspects should be  
24 carefully considered:

- 25 • *nature of effect*: route-to-route extrapolation is only applicable for the  
26 evaluation of systemic effects. For the evaluation of local effects after  
27 repeated exposure, only results from toxicity studies performed with the route  
28 under consideration can be used;
- 29 • *toxicokinetic data (ADME)*: The major factors responsible for differences in  
30 toxicity due to route of exposure include:
  - 31 • differences in bioavailability or absorption,
  - 32 • differences in metabolism (first pass effects),
  - 33 • differences in internal exposure pattern (i.e. internal dose).

34 In the absence of relevant kinetic data, route-to-route extrapolation is only possible if  
35 the following assumptions are reasonable:

- 36 • Absorption can be quantified

- 1           • Toxicity is a systemic effect not a local one (compound is relatively soluble in  
2           body fluids, therefore systemically bioavailable) and internal dose can be  
3           estimated<sup>37</sup>
- 4           • First-pass effects are minimal

5    Provided the listed criteria are met, the only possibility for route-to-route extrapolation is  
6    to use default values. If route-to-route extrapolation is required or if an internal  
7    N(O)AEL/starting point needs to be derived in order to assess combined exposure from  
8    different routes, information on the extent of absorption for the different routes of  
9    exposure should be used to modify the starting point. On a case-by-case basis a  
10   judgement will have to be made as to whether the extent of absorption for the different  
11   routes of exposure determined from the experimental absorption data is applicable to  
12   the starting point of interest. Special attention should be given to the dose ranges  
13   employed in the absorption studies (e.g. very high dose levels) compared to those (e.g.  
14   much lower dose levels, especially in the case of human data) used to determine the  
15   starting point. Consideration should also be given to the age of the animals employed in  
16   the absorption studies (e.g. adult animals) compared to the age of the animals (e.g.  
17   pups during lactation) used to determine the starting point. For substances that undergo  
18   first-pass metabolism by one or more routes of administration, information on the extent  
19   of the presystemic metabolism and systemic availability should also be considered. This  
20   could lead to an additional modification of the starting point.

21   In practice, in the absence of dermal toxicity factors, the US EPA (2004) has devised a  
22   simplified paradigm for making route-to-route (oral-to-dermal) extrapolations for  
23   systemic effects. This approach is subject to a number of factors that might compromise  
24   the applicability of an oral toxicity factor for dermal exposure assessment. The  
25   estimation of oral absorption efficiency, to adjust the toxicity factor from administered to  
26   absorbed dose, introduces uncertainty. Part of this uncertainty relates to distinctions  
27   between the terms absorption and bioavailability. Typically, the term absorption refers to  
28   the disappearance of chemical from the gastrointestinal lumen, while oral bioavailability  
29   is defined as the rate and amount of chemical that reaches the systemic circulation  
30   unchanged. That is, bioavailability accounts for both absorption and pre-systemic  
31   metabolism. Although pre-systemic metabolism includes both gut wall and liver  
32   metabolism, for the most part it is liver first pass effect that plays the major role.

33   In the absence of metabolic activation or detoxification, toxicity adjustment should be  
34   based on bioavailability rather than absorption because the dermal pathway purports to  
35   estimate the amount of parent compound entering the systemic circulation. Simple  
36   adjustment of the oral toxicity factor, based on oral absorption efficiency, does not  
37   account for metabolic by-products that might occur in the gut wall but not the skin, or  
38   conversely in the skin, but not the gut wall.

---

<sup>37</sup> It needs to be ensured that systemic effects are not secondary to local ones. E.g. dermal contact with a substance may also result in direct dermal toxicity, such as allergic contact dermatitis, chemical irritation or skin cancer – effects that might in an early stage lead to systemic responses that consequently are misinterpreted as such.

1 The efficiency of first pass metabolism determines the impact on route-to-route  
2 extrapolation. The adjusted dermal toxicity factor may overestimate the true dose-  
3 response relationship because it would be based upon the amount of parent compound  
4 in the systemic circulation rather than on the toxic metabolite. Additionally,  
5 percutaneous absorption may not generate the toxic metabolite to the same rate and  
6 extent as the GI route.

7 In practice, an adjustment in oral toxicity factor (to account for absorbed dose in the  
8 dermal exposure pathway) is recommended when the following conditions are met: (1)  
9 the toxicity value derived from the critical study is based on an administered dose (e.g.,  
10 delivery in diet or by gavage) in its study design; (2) a scientifically defensible database  
11 demonstrates that the GI absorption of the chemical in question, from a medium (e.g.,  
12 water, feed) similar to the one employed in the critical study, is significantly less than  
13 100% (e.g., <50%). A cut-off of 50% GI absorption is recommended to reflect the  
14 intrinsic variability in the analysis of absorption studies. Thus, this cut-off level obviates  
15 the need to make comparatively small adjustments in the toxicity value that would  
16 otherwise impart on the process a level of accuracy that is not supported by the scientific  
17 literature.

18 If these conditions are not met, a default value of complete (i.e., 100%) oral absorption  
19 may be assumed, thereby eliminating the need for oral toxicity-value adjustment. The  
20 Uncertainty Analysis could note that employing the oral absorption default value may  
21 result in underestimating risk, the magnitude of which being inversely proportional to the  
22 true oral absorption of the chemical in question.

23 The extrapolation of the kinetic behaviour of a chemical from one exposure route to  
24 another can also be performed by using PBK models. This extrapolation procedure is  
25 based on the inclusion of appropriate model equations to represent the exposure  
26 pathways of interest. Once the chemical has reached the systemic circulation, its  
27 biodistribution is assumed to be independent of the exposure route. To represent each  
28 exposure pathway different equations (or models) are typically used. The oral exposure  
29 of a chemical may be modelled by introducing a first order or a zero order uptake rate  
30 constant. To simulate the dermal absorption, a diffusion-limited compartment model  
31 may represent skin as a portal of entry. Inhalation route is often represented with a  
32 simple pulmonary compartment and the uptake is controlled by the blood over air  
33 partition coefficient. After the equations describing the route-specific entry of chemicals  
34 into systemic circulation are included in the model, it is possible to conduct  
35 extrapolations of toxicokinetics and dose metrics.

36 In conclusion, route-to-route extrapolation can follow the application of assessment  
37 factors as long as the mentioned pre-conditions are met. Any specific TK information  
38 may refine the assessment factor in order to meet the precautionary function of the  
39 application of the factors as such.

- Appendix R.7.12-3 PBK Modelling and the Development of Assessment Factors
- Appendix R.7.12-4 Dermal absorption percentage†

1 **Appendix R.7.12-1 Toxicokinetics– Physiological Factors**

2

3 This inventory has been compiled to provide a source of information on physiological  
 4 parameters for various species that may be useful for interpreting toxicokinetic data. The  
 5 list is not exhaustive and data from other peer-reviewed sources may be used. If study-  
 6 specific data are available then this should be used in preference to default data.

7 Zwart *et al.* (1999) have reviewed anatomical and physiological differences between  
 8 various species used in studies on pharmacokinetics and toxicology of xenobiotics. A  
 9 selection of the data presented by these authors that may be relevant in the context of  
 10 the EU risk assessment is quoted below. The tables are adapted from Zwart *et al.*  
 11 (1999).

12 The authors however, focus on the oral route of administration and data relevant for  
 13 other routes may have to be added. Some of those are already quoted in the section on  
 14 repeated dose toxicity and are therefore not repeated here.

15 **Data on stomach pH-values**

16 Qualitative Aspects to be considered in the stomach

17 Rodents have a non-glandular forestomach that has no equivalent in humans. It is thin-  
 18 walled and transparent. In the non-glandular stomach the pH is typically higher than in  
 19 the glandular part and it contains more microorganisms. The glandular stomach has  
 20 gastric glands similar to the human stomach but is a relatively small part of the total  
 21 rodent stomach. Data on stomach pH for different species are rare and most stem from  
 22 relatively old sources.

23 **Table R.7.12–7 Data on stomach pH for different species**

|                          | Human         | Rhesus monkey | Rat | Mouse | Rabbit | Dog                    | Pig               |

4 (from De Sesso, 1993)

5 The US EPA in the Exposure factors handbook (1997) has reviewed a number of studies  
 6 on inhalation rates for different age groups and activities. The activity levels were  
 7 categorized as resting, sedentary, light, moderate and heavy. Based on the studies that  
 8 are critically reviewed in detail in the US EPA document, a number of recommended  
 9 inhalation rates can be derived. One bias in the data is mentioned explicitly, namely that  
 10 most of the studies reviewed were limited to the Los Angeles area and may thus not  
 11 represent the general US population. This should also be born in mind when using those  
 12 data in the European context. The recommended values were calculated by averaging  
 13 the inhalation rates (arithmetic mean) for each population and activity level from the  
 14 various studies. Due to limitations in the data sets an upper percentile is not  
 15 recommended. The recommended values are given below:

16 **Table R.7.12—11 Summary of recommended values from US EPA (1997)**

| Population                       | Mean ventilation rates [m <sup>3</sup> /24 h] |
|----------------------------------|---|
| <b>Long-term exposures</b>       |   |
| Infants <1 year <sup>1)</sup>    | 4.5   |
| Children 1-2 years <sup>1)</sup> | 6.8   |
| 3-5 years <sup>1)</sup>          | 8.3   |
| 6-8 years <sup>1)</sup>          | 10  |
| 9-11 years                       |   |
| males                            | 14  |
| females                          | 13  |
| 12-14 years                      |   |
| males                            | 15  |
| females                          | 12  |

| Population            | Mean ventilation rates [m <sup>3</sup> /24 h] |
|-----------------------|---|
| 15-18 years           |   |
| males                 | 17  |
| females               | 12  |
| Adults 19 – 65+ years |   |
| males                 | 15.2  |
| females               | 11.3  |
| Short-term exposures  | m <sup>3</sup> /h                             |
| Children              |   |
| Rest                  | 0.3   |
| Sedentary activities  | 0.4   |
| Light activities      | 1.0   |
| Moderate activities   | 1.2   |
| Heavy activities      | 1.9   |
| Adults                |   |
| Rest                  | 0.4   |
| Sedentary activities  | 0.5   |
| Light activities      | 1.0   |
| Moderate activities   | 1.6   |
| Heavy activities      | 3.2   |
| Outdoor workers       |   |
| Hourly average        | 1.3 (3.3 m <sup>3</sup> /h) <sup>2)</sup>     |
| Slow activities       | 1.1   |
| Moderate activities   | 1.5   |
| Heavy activities      | 2.5   |

1 <sup>1)</sup> No sex difference found

2 <sup>2)</sup> Upper percentile

3

4 The document also mentions that for a calculation of an endogenous dose using the  
5 alveolar ventilation rate it has to be considered that only the amount of air available for  
6 exchange via the alveoli per unit time has to be taken into account, accounting for

1 approximately 70% of the total ventilation. This should also be considered in the risk  
2 assessment.

3 Using a respiratory tract dosimetry model (ICRP66 model; Snipes *et al.*, 1997)  
4 calculated respiration rates for male adults. Based on these breathing rates estimated  
5 daily volumes of respiration were derived for different populations:

- 6 • General population: 8 h sleep, 8 h sitting, 8 h light activity: 19.9 m<sup>3</sup>
- 7 • Light work: 8 h sleep, 6.5 h sitting, 8.5 h light activity, 1 h heavy activity:  
8 22.85 m<sup>3</sup>
- 9 • Heavy work: 8 h sleep, 4 h sitting, 10 h light activity, 2 h heavy activity:  
10 26.76 m<sup>3</sup>

11 The same authors also mention that in humans breathing pattern changes from nose  
12 breathing to nose/mouth breathing at a ventilation rate of about 2.1 m<sup>3</sup>/h (60% through  
13 nose, 40% through the mouth). At a ventilation rate of 5 m<sup>3</sup>/h about 60% of air is  
14 inhaled through the mouth and 40% through the nose. However these model  
15 calculations seem to overestimate the ventilation rates compared to the experimental  
16 data reviewed by US EPA (1992).

### 17 **Physiological parameters used in PBK modeling**

18 Literature on PBK modelling also contains a number of physiological parameters that are  
19 used to calculate tissue doses and distributions. Brown *et al.* (1997) have published a  
20 review of relevant physiological parameters used in PBK models. This paper provides  
21 representative and biologically plausible values for a number of physiological parameters  
22 for common laboratory species and humans. It constitutes an update of a document  
23 prepared by Arms and Travis (1988) for US EPA and also critically analyses a compilation  
24 of representative physiological parameter values by Davies and Morris (1993). Those  
25 references are therefore not reviewed here, but given in the reference list for  
26 consultation. In contrast to the other authors Brown *et al.* (1997) also try to evaluate  
27 the variability of the parameters wherever possible, by giving mean values plus standard  
28 deviation and/or the range of values identified for the different parameters in different  
29 studies. The standard deviations provided are standard deviations of the reported means  
30 in different studies, in other words they are a measure of the variation among different  
31 studies, not the interindividual variation of the parameters themselves. This variation  
32 may therefore include sampling error, interlaboratory variation, differences in techniques  
33 to obtain the data. The authors also provide some data on tissues within certain organs,  
34 which will not be quoted here.

1 **Table R.7.12–12 Organ weights as percent of body weight**

2 (adapted from Brown *et al.* (1997)) (Typically the values reflect weights of organs drained of  
3 blood)

| Organ                       | Mouse mean ± standard deviation | Mouse range         | Rat mean ± standard deviation | Rat range            | Dog mean ± standard deviation | Dog range     | Human reference value mean ± standard deviation                        | Human range             |

12 To derive the organ volume from the mass for most organs a density of 1 can reasonably  
13 be assumed. The density of marrow free bone is 1.92 g/cm<sup>3</sup> (Brown *et al.*, 1997).

14 Brown *et al.* (1997) also give values for cardiac output and regional blood flow as a  
15 percentage of cardiac output or blood flow/100 g tissue weight for the most common  
16 laboratory species and humans. The data used are derived from non-anaesthetised  
17 animals using radiolabelled microsphere technique. For humans data using various  
18 techniques to measure perfusion were compiled.

19

3 <sup>1)</sup> One study only

4 According to the authors giving blood flow in units normalised for tissue weight can  
5 result in significant errors if default reference weights are used instead of measured  
6 tissue weights in the same study.

7 **Table R.7.12–14 Regional blood flow distribution in different species**

8 (ml/min/100g of tissue) (adopted from Brown *et al.* (1997))

3 <sup>1)</sup> Bronchial flow

4 <sup>2)</sup> One study only

5 The blood flow to some organs such as the liver are highly variable and can be  
 6 influenced by factors including anaesthesia, posture, food intake, exercise.

7

8 Gerlowski and Jain (1983) have published a compilation of different organ volumes and  
 9 plasma flows for a number of species at a certain body weight from other literature  
 10 sources.

1 **Table R.7.12–16 Organ volumes, plasma flow used in PBK-models**

| Parameter                   | Mouse | Hamster | Rat   | Rabbit | Monkey | Dog    | Human  |
|-----------------------------|-------|---------|-------|--------|--------|--------|--------|
| Body weight (g)             | 22    | 150     | 500   | 2,330  | 5,000  | 12,000 | 70,000 |

3 Gad and Chengelis (1992) have summarised a number of physiological parameters for  
 4 different species. The most important data of the most common laboratory test species  
 5 are summarised below.

1 **Table R.7.12–18 A number of physiological parameters for different species**  
 2 (Blaauboer *et al.*, 1996)

|   | Rat         | Mouse          | Guinea Pig  | Rabbit   | Dog<br>(Beagle)      |
|---|-------------|----------------|-------------|----------|----------------------|
| Blood volume whole blood (ml/kg)        | 57.5 - 69.9 | 78             | 75          | 45 - 70  | -                    |
| Blood volume Plasma (ml/kg)             | 36.3 - 45.3 | 45             | 30.6 - 38.2 | -        | -                    |
| Respiratory frequency min <sup>-1</sup> | 66 - 114    | 84 - 230       | 69 - 160    | 35 - 65  | 10 - 30 <sup>1</sup> |

## 1 **Appendix R.7.12-2 Prediction of toxicokinetics integrating** 2 **information generated *in silico* and *in vitro***

3

4 The methods presented in this attachment are for the purpose to demonstrate the future  
5 use of *in silico* and/or *in vitro* methods in toxicokinetics. Although promising in the area  
6 of pharmaceutical research, most of the examples given have not been fully validated for  
7 the purpose of use outside this area. Further development and validation of these  
8 approaches are ongoing.

9 Techniques for the prediction of pharmacokinetics in animals or in man have been used  
10 for many years in the pharmaceutical industry, at various stages of research and  
11 development. A considerable amount of work has been dedicated to developing tools to  
12 predict absorption, distribution, metabolism, and excretion of drug candidates. The  
13 objective in drug development is to eliminate as early as possible candidate drugs  
14 predicted to have undesirable characteristics, such as being poorly absorbed by the  
15 intended route of administration, being metabolised via undesirable pathways, being  
16 eliminated too rapidly or too slowly. These predictions are done at various stages of drug  
17 development, using all available evidence and generating additional meaningful  
18 information from simple experiments. Although these techniques were developed in the  
19 particular context of drug development, there is no reason a priori not to use them for  
20 the safety assessment of chemicals. The toxicokinetic information generated can be used  
21 in particular to select substances to be further developed, to direct further testing and to  
22 assist experimental design, thus saving experimental efforts in terms of cost, time and  
23 animal use.

24 In practice, the prediction of the toxicokinetic behaviour of a chemical rests upon the use  
25 of appropriate models, essentially physiologically-based compartmental pharmacokinetic  
26 models, coupled to the generation of estimates for the relevant model parameters. *In*  
27 *silico* models or *in vitro* techniques to estimate parameter values used to predict  
28 absorption, metabolic clearance, distribution and excretion have been developed.  
29 Blaauboer *et al.* (1996; 2002) reviewed the techniques involved in toxicokinetic  
30 prediction using physiologically-based kinetic models. The thorough discussion on the  
31 applicability of physiologically based pharmacokinetic models in risk assessment is  
32 provided by IPCS (2010). Also, a general discussion on the *in silico* methods used to  
33 predict ADME is provided by Boobis *et al.* (2002).

34 As for all predictions using models, these approaches must be considered together with  
35 the accompanying uncertainty of the predictions made, which have to be balanced  
36 against the objective of the prediction. Experimental validation *in vivo* of the predictions  
37 made and refinement of the models used is usually necessary (Parrott *et al.*, 2005; US  
38 EPA, 2007), and has to be carefully planned on a case by case basis. A strategy for  
39 integrating predicted and experimental kinetic information generated routinely during  
40 drug development is described by Theil *et al.* (2003), by Parrot *et al.* (2005), and by  
41 Jones *et al.* (2006). The principles presented by these authors are relevant to kinetics  
42 simulation and prediction in the field of chemical safety, since they allow the integration  
43 of the available kinetic or kinetically-relevant information from the very beginning of the  
44 risk assessment process. In the most initial stages of development, simulations can be

1 generated using only physico-chemical characteristics, which themselves can be derived  
2 from *in silico* models (QSARs/ QSPRs).

3 The strategy proposed by Jones *et al.* (2006), in the compound set investigated, led to  
4 reasonably accurate prediction of pharmacokinetics in man for approximately 70% of the  
5 compounds. According to the authors, *these successful predictions were achieved mainly*  
6 *for compounds that were cleared by hepatic metabolism or renal excretion, and whose*  
7 *absorption and distribution were governed by passive processes. Significant mis-*  
8 *predictions were achieved when other elimination processes (e.g. biliary elimination) or*  
9 *active processes were involved or when the assumptions of flow limited distribution and*  
10 *well mixed compartments were not valid.*

11 In addition to the parent compound, in a number of cases metabolites contribute  
12 significantly or even predominantly, to the overall exposure-response relationship. In  
13 such cases, the quantitative *ex vivo* prediction of metabolite kinetics after exposure to  
14 the parent compound remains difficult. A separate study program of the relevant  
15 metabolites may then become necessary.

## 16 **Models used to predict absorption / bioavailability**

### 17 Gastro intestinal absorption models

18 In order to be absorbed from the GI tract, substances have to be present in solution in  
19 the GI fluids, and from there have to cross the GI wall to reach the lymph or the venous  
20 portal blood. Key determinants of gastrointestinal absorption are therefore:

- 21 • release into solution from solid forms or particles (dissolution),
- 22 • solubility in the GI fluids, and
- 23 • permeability across the GI wall into the circulatory system.

24 Dokoumetzidis *et al.* (2005) distinguish two major approaches in the modelling of the  
25 drug absorption processes involved in the complex milieu of the GI tract.

26 The first approach is the simplified description of the observed profiles, using simple  
27 differential or algebraic equations. On this basis, a simple classification for  
28 pharmaceutical substances, the Biopharmaceutics Classification System (BCS), resting  
29 on solubility and intestinal permeability considerations, has been developed by Amidon  
30 *et al.* (1995). The BCS divides pharmaceutical substances into 4 classes according to  
31 their high or low solubility and to their high or low intestinal permeability, and has been  
32 incorporated into FDA guidance (2000).

33 The second approach tries to build models incorporating in more detail the complexity of  
34 the processes taking place in the intestinal lumen, using either compartmental analysis,  
35 i.e. systems of several differential equations (Agoram *et al.*, 2001; Yu *et al.*, 1996; Yu  
36 and Amidon, 1999), dispersion systems with partial differential equations (Ni *et al.*,  
37 1980; Willmann *et al.*, 2003 and 2004), or Monte Carlo simulations (Kalampokis *et al.*,  
38 1999). Some of these approaches have been incorporated into commercial computer  
39 software (Coecke *et al.*, 2006; Parrott and Lave, 2002), or are used by contract research  
40 organisations to generate predictions for their customers. An attractive feature of these  
41 models is their ability to generate a prediction of extent and often rate of absorption in

1 data-poor situations, i.e. at the initial stage of data generation, using a simple set of  
2 parameters describing ionisation, solubility and permeability.

3 Factors potentially complicating the prediction of absorption are:

- 4 • intra luminal phenomena such as degradation or metabolism, matrix effects,  
5 chemical speciation, which may reduce the amount available for absorption,  
6 or generate metabolites which have to be considered in terms of toxicological  
7 and toxicokinetic properties;
- 8 • intestinal wall metabolism, which may have similar consequences;
- 9 • intestinal transporters (efflux pumps), which may decrease the permeability of  
10 the GI wall to the substance.

11 These factors have to be considered and incorporated into absorption / bioavailability  
12 models on a case-by-case basis.

### 13 *Parameter estimation for GI absorption models*

14 A discussion on the *in vitro* approaches used to generate absorption parameters can be  
15 found in Pelkonen *et al.* (2001).

16 Where relevant, i.e. when dissolution from solid particles may be the limiting factor for  
17 GI absorption, estimates for the dissolution rate parameters can be obtained  
18 experimentally *in vitro* or using a QSAR/ QSPR approach (e.g. Zhao *et al.*, 2002).  
19 Potentially rate-limiting steps preceding dissolution (e.g. disaggregation of larger solid  
20 forms) are usually studied in to a greater extent in the pharmaceutical field than in  
21 chemical safety assessment, because they can be manipulated via formulation  
22 techniques. However, pre-dissolution events may also have a determining role in the  
23 absorption of chemicals, by influencing either its rate or its extent.

24 Solubility parameters can be estimated experimentally or using QSAR/ QSPR models. A  
25 discussion of *in silico* models can be found in Stenberg *et al.* (2002).

26 Permeability estimates can be obtained via:

- 27 • *in silico* models (QSAR/ QSPRs);
- 28 • *in vitro* permeation studies across lipid membranes (e.g. PAMPA) or across a  
29 monolayer of cultured epithelial cells (e.g. CaCO-2 cells, MDCK cells);
- 30 • *in vitro* permeation studies using excised human or animal intestinal tissues;
- 31 • *in vivo* intestinal perfusion experiments, in animals or in humans.

32 Discussion of the various *in silico* and *in vitro* methods to estimate intestinal permeability  
33 can be found in Stenberg *et al.* (2002), Artursson *et al.* (2001), Tavelin *et al.* (2002),  
34 Matsson *et al.* (2005).

### 35 Dermal route

36 Percutaneous absorption through intact skin is highly dependent on the physico-chemical  
37 properties of chemicals, and in particular of molecular weight and lipophilicity. Molecules  
38 above a certain molecular weight are unlikely to cross intact skin, and substances which

1 are either too lipophilic or too hydrophilic have a low skin penetration. Cut off points at a  
2 molecular weight of 500 and log P values below -1 or above 4 have been used to set a  
3 conservative default absorption factor at 10 % cutaneous absorption (EC, 2007).  
4 However, it should be emphasised that this is a default factor, and by no means a  
5 quantitative estimate of cutaneous absorption.

6 Predictive models have been developed to try and estimate the extent of dermal  
7 absorption from physico-chemical properties (Cleek and Bunge, 1993). An *in vitro*  
8 method has been developed and validated and is described in EU B.45<sup>38</sup> or OECD TG  
9 428.

10 The EU funded project on the Evaluation and Prediction of Dermal Absorption of Toxic  
11 Chemicals (EDETTOX) established a large critically evaluated database with *in vivo* and *in*  
12 *vitro* data on dermal absorption / penetration of chemicals. The data were used to  
13 evaluate existing QSARs and to develop new models including a mechanistically-based  
14 mathematical model, a simple membrane model and a diffusion model of percutaneous  
15 absorption kinetics. A guidance document was developed for conduct of *in vitro* studies  
16 of dermal absorption/penetration. More information on the database, model and  
17 guidance documents can be found at <http://www.ncl.ac.uk/edetox/> .

#### 18 Inhalation route

19 Together with physiological values (ventilation flow, blood flow), the key parameter  
20 needed to predict the passage into blood of inhaled volatile compounds is the blood/air  
21 partition coefficient (Blaauboer *et al.*, 1996; Reddy *et al.*, 2005). References to methods  
22 for estimating or measuring blood/air partition coefficients are indicated below together  
23 with the discussion of other partition coefficients. The parameters are included in  
24 physiologically-based models predicting the concentrations in the venous pulmonary  
25 blood, assimilated to the systemic arterial blood, and in the exhaled air.

26 Other factors may influence absorption by the inhalation route. For example, water  
27 solubility determines solubility in the mucus layer, which may be a limiting factor, and  
28 the dimensions of the particles are a key factor for the absorption of particulate matter.

#### 29 Other routes

30 Other routes, e.g. via the oral, nasal or ocular mucosa, may have to be considered in  
31 specific cases.

### 32 **Systemic bioavailability and first-pass considerations**

33 After oral exposure, systemic bioavailability is the result of the cumulated effects of the  
34 absorption process and of the possible extraction by the liver from the portal blood of  
35 part of the absorbed dose, or first-pass effect. The first-pass effect can be incorporated  
36 into a suitably defined physiologically-based toxicokinetic model. Using estimates of both  
37 the absorption rate and of the intrinsic hepatic clearance, the systemic bioavailability of  
38 the substance can then be predicted. Metabolism at the port of entry can also occur  
39 within the gut wall, and this can be included in the kinetic models. At the model

---

<sup>38</sup> See Test Methods Regulation (Council Regulation (EC) No 440/2008).

1 validation stage, however, it is often difficult to differentiate gut wall metabolism from  
2 liver metabolism *in vivo*.

3 Similarly, metabolism may occur in the epidermis or dermis. The current skin absorption  
4 test (EU B.45<sup>39</sup>, OECD TG 428) does not take cutaneous metabolism into account.  
5 Specific studies may be necessary to quantify skin metabolism and bioavailability by  
6 dermal route.

7 Pulmonary metabolism of some substances exist (Borlak *et al.*, 2005), but few  
8 substances are reported to undergo a quantitatively important pulmonary first-pass  
9 effect.

## 10 **Models to predict Distribution**

### 11 Blood binding

#### 12 *Blood cell partitioning*

13 Partitioning of compounds into blood cells, and in particular red blood cells (RBC), is an  
14 important parameter to consider in kinetic modelling (Hinderling, 1997).

15 Partitioning into leukocytes or even platelets may have to be considered in rare cases. A  
16 significant influence of such partitioning has been described for some drugs, e.g.  
17 chloroquine (Hinderling, 1997).

18 Partitioning into blood cells can be measured experimentally *in vitro* (Hinderling, 1997),  
19 or estimated using a QSAR/ QSPR approach based on physico-chemical properties.

#### 20 *Plasma protein binding*

21 Plasma protein binding is an important parameter to be included in physiologically-based  
22 kinetic models, because plasma protein binding can influence dramatically distribution,  
23 metabolism and elimination. Plasma binding with high affinity will often restrict  
24 distribution, metabolism and elimination. However, this is by no means systematic,  
25 because the overall kinetics is a function of the interplay of all processes involved.  
26 Distribution will depend on the balance between affinity for plasma components and for  
27 tissues, and the elimination of compounds having a very high intrinsic clearance (i.e.  
28 very effective elimination mechanisms) will be hastened by high plasma protein binding,  
29 which causes more compound to be available for clearance in the blood compartment.

30 Plasma protein binding is measured using *in vitro* techniques, using either plasma or  
31 solutions of specific proteins of known concentrations. The most standard techniques are  
32 equilibrium dialysis and ultrafiltration, but numerous other techniques have been  
33 described. More detailed information and references are given by Zini (1991) and  
34 Roberts (2001). QSAR/ QSPR methods have also been used to predict of protein binding  
35 affinity (e.g. Colmenarejo, 2003).

---

<sup>39</sup> See Test Methods Regulation (Council Regulation (EC) No 440/2008).

1 Tissue distribution

2 *Blood flow-limited distribution.*

3 In physiologically-based kinetic models, the most common model to describe distribution  
4 between blood and tissue is blood flow-limited distribution, i.e. the equilibrium between  
5 tissue and blood is reached within the transit time of blood through the tissue. In this  
6 model, the key parameters are the partition coefficients. Partition coefficients express  
7 the relative affinity of the compound for the various tissues, relative to a reference fluid  
8 which may be the blood, the plasma or the plasma water. Tissue/ blood, tissue/ plasma,  
9 and tissue/ plasma water partition coefficients are inter-related via plasma protein  
10 binding and blood cell partitioning. Partition coefficients are integrated in the differential  
11 equations predicting blood and tissue concentrations, or in equations of models  
12 predicting globally the steady-state volume of distribution of the compound (Poulin and  
13 Theil, 2002).

14 *Permeability-limited distribution*

15 In some cases however, due to a low permeability of the surface of exchange between  
16 blood and a particular tissue (e.g. blood-brain barrier, placental barrier), the equilibrium  
17 between blood and tissue cannot be reached within the transit time of blood through the  
18 tissue, and a correction factor must be introduced in the differential equation describing  
19 distribution to that tissue. One common, simple way of doing this is to use the  
20 permeability area cross product. Thus, distribution is in this case determined by the  
21 arterial concentration and the three factors blood flow (physiological parameter),  
22 permeability per unit of surface (compound-specific parameter), and surface of exchange  
23 (physiological parameter; see Reddy *et al.*, 2005). Permeability-limited distribution  
24 makes prediction more difficult due to the lack of well-recognised, easy to use and  
25 robust models to quantify the necessary parameters.

26 Determination of partition coefficients

27 Experimental methods available to obtain blood/ air, tissue/ air and blood/ tissue  
28 partition coefficients are discussed by Krishnan and Andersen (2001). *In vitro* methods  
29 include vial equilibration (for volatile compounds), equilibrium dialysis and ultrafiltration.  
30 However, these methods require ex-vivo biological material, are time-consuming and  
31 often require the use of radiolabelled compound (Blaauboer, 2002).

32 Models to calculate predicted tissue/blood, tissue/plasma or tissue/plasma water  
33 partition coefficients from simple physico-chemical properties have been developed  
34 (Poulin and Theil, 2002; Rodgers *et al.*, 2005 and 2006). The necessary compound-  
35 specific input is limited to knowledge of the chemical structure and functionalities (e.g.  
36 neutral, acid, base, zwitterionic), the pKa or pKas where applicable, and the octanol-  
37 water partition coefficient at pH 7.4. Additional necessary parameters describe the tissue  
38 volumes and tissue lipid composition. Tissue volumes are usually available or can be  
39 estimated from the literature. There are less available direct data on tissue composition  
40 in terms of critical binding constituents, particularly in man, although some reasonable  
41 estimates can be made from the existing information.

42 QSAR/ QSPR models developed for the estimation of blood/air and tissue/blood partition  
43 coefficients have also been reported (Blaauboer, 2002).

## 1 Prediction of metabolism

2 Numerous aspects of metabolism can and often should be explored using *in vitro*  
3 methods (Pelkonen *et al.*, 2005).

4 Major objectives of the study of metabolism using *in vitro* methods are:

- 5 • determining the susceptibility of a chemical to metabolism (its metabolic  
6 stability);
- 7 • identifying its kinetically and toxicologically relevant metabolites in the species  
8 of interest (including man);
- 9 • obtaining a quantitative global estimate of its metabolic clearance, to be  
10 included in toxicokinetic models.

11 Additional possible objectives are:

- 12 • characterising enzyme kinetics of the principal metabolic reactions, which can  
13 also be used for scaling up and predicting *in vivo* kinetics of a new chemical;
- 14 • estimating the ability of the chemical to act as a substrate for the different  
15 enzymes involved in biotransformation;
- 16 • exploring inter-species differences in metabolism;
- 17 • evaluating potential variability in metabolism in a given species, man in  
18 particular;
- 19 • identifying whether the chemical and/or its metabolite can act as an enzyme  
20 inducer;
- 21 • identifying whether the chemical and/or its metabolite can act as an enzyme  
22 inhibitor, and the type of inhibition involved.

23 Most methods have been developed in the pharmaceutical field, and focused on the  
24 cytochrome P isoforms (CYP), because these are the major enzymes involved in drug  
25 metabolism. The extension of existing methods to a wider chemical space, and to other  
26 enzymatic systems, such as other oxidation pathways, acetylation, hydrolysis, needs to  
27 be undertaken with caution, and methods are bound to evolve in this context. In any  
28 case, the study of metabolism *in vitro* is often an important step in the integrated risk  
29 assessment of chemicals. In many cases *in vitro* methods are the only option to study  
30 metabolism, due to the impracticality or sheer impossibility of *in vivo* studies.

### 31 Relative role of different organs in metabolism

32 Quantitatively, the most important organ for metabolism is by far the liver, although  
33 metabolism by other organs can be important quantitatively or qualitatively. The nature  
34 of the chemical and the route of administration must be taken into account when  
35 assessing which organs are most relevant in terms of metabolism (Coecke *et al.*, 2006).

### 36 *In vitro* methods to study metabolism

37 *In vitro* methods to explore the metabolism, and particularly the hepatic metabolism of a  
38 substance are thoroughly discussed by Pelkonen *et al.* (2005) and Coecke *et al.* (2006).

1 Depending on the objective, the different metabolising materials used are microsomes  
2 and microsomal fractions, recombinant DNA-expressed individual CYP enzymes,  
3 Immortalised cell lines, primary hepatocytes in culture or in suspension, liver slices.

#### 4 Quantitative estimation of the intrinsic clearance of a substance.

5 One of the most important pieces of information in order to simulate the toxicokinetics of  
6 a substance is the intrinsic metabolic clearance *in vivo*, which has to be incorporated into  
7 the kinetic models. Intrinsic clearance can be estimated using quantitative *in vitro*  
8 systems (purified enzymes, microsomes, hepatocytes) and extrapolating the results to  
9 the *in vivo* situation.

10 If only a single or a few concentrations are tested, the intrinsic clearance can only be  
11 expressed as a single first-order elimination parameter, ignoring possible saturation  
12 phenomena. The latter can only be detected by testing a large enough concentration  
13 range in an appropriately chosen system. For instance, if a Michaelis and Menten model  
14 is applicable, both the  $V_{\max}$  and the  $K_m$  of the system may be thus determined.

15 Of particular importance are:

- 16 • the quality and characterisation of the metabolising system itself;
- 17 • the quality and characterisation of the experimental conditions, in particular  
18 as regards the system's capacity for binding the substances under study  
19 (Blanchard *et al.*, 2005) but obviously also as regards other parameters such  
20 as temperature, pH, etc.
- 21 • The use of appropriate scaling factors to extrapolate to predicted clearance  
22 values *in vivo*.

23 Scaling factors must be chosen taking into account the *in vitro* system utilised. They  
24 incorporate in particular information on the *in vitro* concentration of chemical available to  
25 the metabolising system (unbound), the nature and amount of the enzymes present in  
26 the *in vitro* system, the corresponding amount of enzymes in hepatocytes *in vivo*, and  
27 the overall mass of active enzyme in the complete liver *in vivo*. Discussions on the  
28 appropriate scaling procedures and factors to be taken into account have been  
29 developed by Houston and Carlile (1997), Inoue *et al.* (2006), Shiran *et al.* (2006),  
30 Howgate *et al.* (2006), Johnson *et al.* (2005), Proctor *et al.* (2004).

#### 31 *In vitro* screening for Metabolic interactions

32 *In vitro* screening procedures for the prediction of metabolic interactions have been  
33 developed for pharmaceuticals. They involve testing an *in vitro* metabolising system for  
34 a number of well characterised compounds, with and without the new substance  
35 (Blanchard *et al.*, 2004; Turpeinen *et al.*, 2005).

#### 36 Prediction of excretion

37 The most common major routes of excretion are renal excretion, biliary excretion and,  
38 for volatile compounds, excretion via expired air.

39 There is at present no *in vitro* model to reliably predict biliary or renal excretion  
40 parameters. Determining factors include molecular weight, lipophilicity, ionisation,

1 binding to blood components, and the role of active transporters. In the absence of  
2 specific a priori information, many kinetic models include non-metabolic clearance as a  
3 single first order rate excretion parameter.

#### 4 Expired air (exhalation clearance)

5 Excretion into expired air is modelled using the blood/ air partition coefficient, as  
6 described in [Appendix R.7.12-2](#) (Reddy *et al.*, 2005).

#### 7 Biliary clearance

8 Current work on biliary excretion focuses largely on the role of transporters (e.g.  
9 Klaassen, 2002; Klaassen and Slitt, 2005). However, experimentally determined  
10 numerical values for parameters to include into modelling of active transport are largely  
11 missing, so that these mechanisms cannot yet be meaningfully included in kinetic  
12 models. Levine (1978), Rollins and Klaassen (1979) and Klaassen (1988) have reviewed  
13 classical information on the biliary excretion of xenobiotics. Information in man is still  
14 relatively scarce, given the anatomical and ethical difficulties of exploring biliary  
15 excretion directly in man. Compounds may be highly concentrated into the bile, up to a  
16 factor of 1000, and bile flow in man is relatively high, between 0.5 and 0.8 ml/min, so  
17 that considerable biliary clearance values of several hundred ml/min, can be achieved  
18 (Rowland and Tozer, 1989; Rowland *et al.*, 2004). It should be considered on a case-by-  
19 case basis whether biliary excretion and possible entero-hepatic recirculation should be  
20 included in the kinetic models used for prediction.

#### 21 Renal clearance

22 In healthy individuals and in most pathological states, the renal clearance of xenobiotics  
23 is proportional to the global renal function, reflected in the glomerular filtration rate,  
24 which can be estimated *in vivo* by measuring or estimating the clearance of endogenous  
25 creatinine. Simple models for renal clearance consider only glomerular filtration of the  
26 unbound plasma fraction. However, this can lead to significant misprediction when active  
27 transport processes are involved. More sophisticated models have been described which  
28 include reabsorption and / or active secretion of xenobiotics (Brightman *et al.*, 2006;  
29 Katayama *et al.*, 1990; Komiya, 1986 and 1982), but there are insufficient input or  
30 reference data to both implement such models and evaluate satisfactorily their  
31 predictivity.

#### 32 Kinetic modelling programs

33 A number of programs for toxicokinetics simulation or prediction are either available, or  
34 used by contract research companies to test their customer's compounds. A non-  
35 comprehensive list of such programs is given by Coecke *et al.*, (2006). Available  
36 physiologically-based modelling programs purpose-built for toxicokinetic prediction  
37 include (non-comprehensive list):

- 38 • SimCYP® (SimCYP Ltd, [www.simcyp.com](http://www.simcyp.com));
- 39 • PK-Sim® (Bayer Technology Services GmbH, [www.bayertechnology.com](http://www.bayertechnology.com));
- 40 • GastroPlus™ (Simulations Plus Inc, [www.simulations-plus.com](http://www.simulations-plus.com));
- 41 • Cloe PK® (Cyprotex Plc, [www.cyprotex.com](http://www.cyprotex.com));

- 1           • Noraymet ADME™ (Noray Bioinformatics, SL, [www.noraybio.com](http://www.noraybio.com)).
- 2       Numerous other simulation programs, either general-purpose or more specifically
- 3       designed for biomathematical modelling, can be used to implement PBK models. A
- 4       discussion on this subject and a non-comprehensive list can be found in Rowland *et al.*
- 5       (2004).
- 6

### 1 **Appendix R.7.12-3 PBK Modelling and the Development of** 2 **Assessment Factors**

3

4 A simple but fictional example of the development of an assessment factor for  
5 interspecies differences using PBK modelling is presented. A fictional chemical,  
6 compound A, is a low molecular weight, volatile solvent, with potential central nervous  
7 system (CNS) depressant properties. Evidence for the latter comes from a number of  
8 controlled human volunteer studies where a battery of neurobehavioural tests were  
9 conducted during, and after, exposure by inhalation to compound A.

10 Compound A is metabolised *in vitro* by the phase I, mixed-function oxidase enzyme,  
11 cytochrome P450 2E1 (CYP2E1) by both rat and human hepatic microsomes. There are  
12 also some *in vivo* data in rats exposed by inhalation to compound A, with and without  
13 pre-treatment with diallyl sulphide, an inhibitor of CYP2E1, that are consistent with  
14 metabolism of compound A by this enzyme.

15 PBK models for the rat and standard human male or female for exposure by inhalation to  
16 compound A are built. The rat model was validated by simulating experimentally  
17 determined decreases in chamber concentrations of compound A following exposure of  
18 rats to a range of initial concentrations in a closed-recirculated atmosphere exposure  
19 chamber. The removal of chamber concentration of compound A over time is due to  
20 uptake by the rat and elimination, primarily by metabolism. The human PBK model was  
21 validated by simulating experimentally determined venous blood concentrations of  
22 compound A in male and female volunteers exposed by inhalation to a constant  
23 concentration of compound A in a controlled-atmosphere exposure chamber.

24 It is assumed that the following have been identified for the chemical: 1) the active  
25 moiety of the chemical, and 2) the relevant dose-metric (i.e., the appropriate form of  
26 the active moiety e.g., peak plasma concentration (C<sub>max</sub>), area-under-the-curve of  
27 parent chemical in venous blood (AUCB), average amount metabolised in target tissue  
28 per 24 hours (AM<sub>met</sub>), peak rate of hepatic metabolism (AM<sub>PeakMet</sub>), etc). In this case,  
29 it is hypothesised that the peak plasma concentration C<sub>max</sub> of compound A is the most  
30 likely surrogate dose metric for CNS concentrations of compound A thought to cause a  
31 reversible CNS depressant effect. However, C<sub>max</sub>, is dependent upon the peak rate of  
32 hepatic metabolism (AM<sub>PeakMet</sub>). Therefore, the validated rat and human PBK models  
33 were run to simulate the exposure time and concentrations of the human study where  
34 the neurobehavioural tests did not detect any CNS depressant effects. The dose metric,  
35 AM<sub>PeakMet</sub> for the rat would be divided by the AM<sub>PeakMet</sub> for the human. This ratio  
36 would represent the magnitude of the difference between a specified rat strain and  
37 average human male or female. This value may then replace the default interspecies  
38 kinetic value since it is based on chemical-specific data. Therefore, the derivation of an  
39 appropriate assessment factor in setting a DNEL can be justified more readily using  
40 quantitative and mechanistic data.

41

1 **Appendix R.7.12-4 Dermal absorption percentage†**

2 † Based on *in vivo* rat studies in combination with *in vitro* data and a proposal for a  
 3 tiered approach to risk assessment (Benford *et al.*, 1999).

4  
 5 Estimation of dermal absorption percentage. If appropriate dermal penetration data are  
 6 available for rats *in vivo* and for rat and human skin *in vitro*, the *in vivo* dermal  
 7 absorption in rats may be adjusted in light of the relative absorption through rat and  
 8 human skin *in vitro* under comparable conditions (see equation below and [Figure](#)  
 9 [R.7.12–4](#)). The latter adjustment may be done because the permeability of human skin  
 10 is often lower than that of animal skin (e.g., Howes *et al.*, 1996). A generally applicable  
 11 correction factor for extrapolation to man can however not be derived, because the  
 12 extent of overestimation appears to be dose, substance, and animal specific (ECETOC,  
 13 2003; Howes *et al.*, 1996; Bronaugh and Maibach, 1987). For the correction factor based  
 14 on *in vitro* data, preferably maximum flux values should be used. Alternatively, the  
 15 dermal absorption percentage (receptor medium plus skin dose) may be used. Because,  
 16 by definition, the permeation constant (Kp in cm/hr) is established at infinite dose levels,  
 17 the usefulness of the Kp for dermal risk assessment is limited.

18 
$$\textit{in vivo} \text{ human absorption} = \frac{\textit{in vivo} \text{ animal absorption} \times \textit{in vitro} \text{ human absorption}}{\textit{in vitro} \text{ animal absorption}}$$

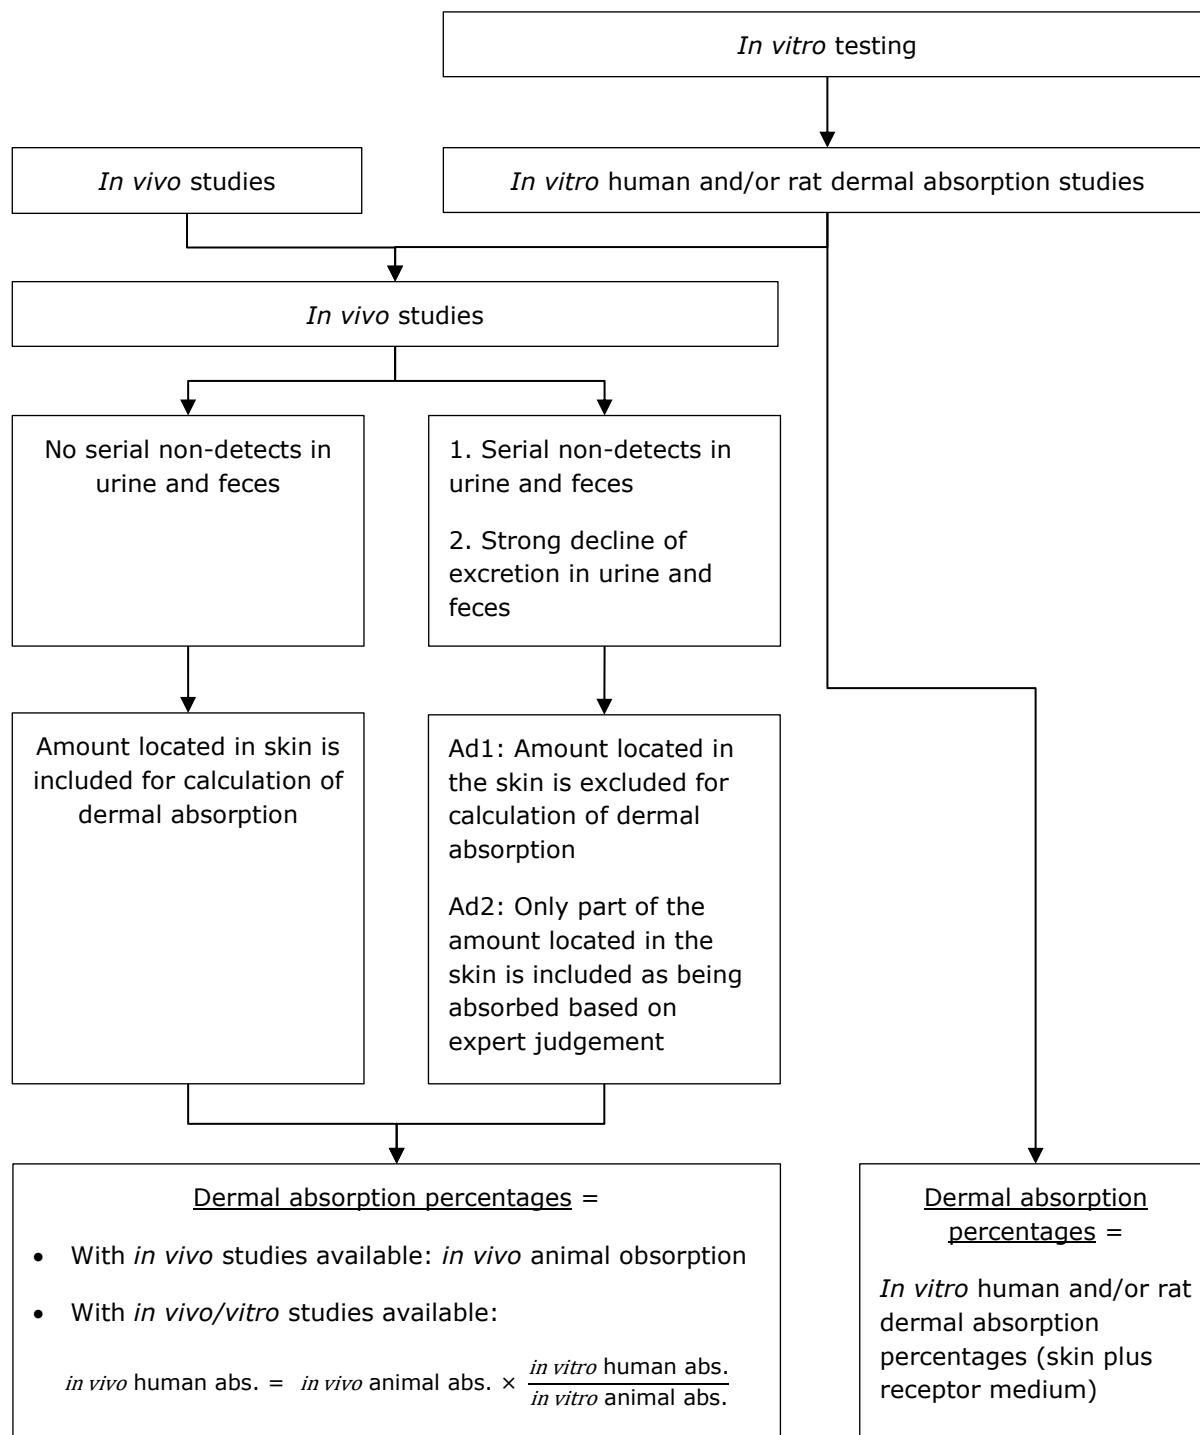

19 Similar adjustments can be made for differences between formulants (e.g. *in vivo* active  
 20 substance in rat and *in vitro* rat data on formulants and active substance)

21 Tiered Risk Assessment. The establishment of a value for dermal absorption may be  
 22 performed by use of a tiered approach from a worst case to a more refined estimate (see  
 23 [Figure R.7.12–4](#)). If an initial assessment ends up with a risk, more refinement could be  
 24 obtained in the next tier if more information is provided on the dermal absorption. In a  
 25 first tier of risk assessment, a worst case value for dermal absorption of 100% could be  
 26 used for external dermal exposure in case no relevant information is available (Benford  
 27 *et al.*, 1999). An estimate of dermal absorption could be made by considering other  
 28 relevant data on the substance (e.g., molecular weight, log P<sub>ow</sub> and oral absorption data)  
 29 (second tier) or by considering experimental *in vitro* and *in vivo* dermal absorption data  
 30 (third tier, see Section [R.7.12.2.2](#)). If at the end of the third tier still a risk is calculated,  
 31 the risk assessment could be refined by means of actual exposure data (fourth tier)  
 32 ([Figure R.7.12–4](#)). This approach provides a tool for risk assessment, and in general it  
 33 errs on the safe side.

34

### R.7.13 Substances requiring special considerations regarding testing and exposure

Standard approaches for hazard and risk characterisation rely on the premise that human and/or environmental exposure to a certain substance is adequately represented by the exposure of the test substance used in standard test protocols. However, there may be situations where the composition of a substance to which human and/or environmental exposure occurs, could be different from that tested in the laboratory studies. For example substances with variability in composition may result in a similar variation in the exposure profile of the different components over time. Also the composition of a liquid that is a complex mixture might be very different from that of its associated vapour phase or the Water Accommodated Fraction (WAF) and it is therefore necessary to develop a specific testing strategy to ensure that the composition of the sample to be tested in the laboratory reflects fully the composition of the likely human or environmental exposure. Such substances are designated as *Non-standard substances*, *Complex Substances* or *Substance of Unknown or Variable composition*, *Complex reaction products* or *Biological material* (UVCB substances) and have generally the following characteristics:

- they contain numerous chemicals (typically closely related isomers and/or chemical classes with defined carbon number or distillation ranges), and cannot be represented by a simple chemical structure or defined by a specific molecular formula
- they are not intentional mixtures of chemicals.
- many are of natural origin (e.g., crude oil, coal, plant extracts) and cannot be separated into their constituent chemical species.
- the concept of *impurities* typically does not apply to complex substances.
- they are produced according to a performance specification related to their physico-chemical properties.

This class of substances requires a case-by-case consideration of the approach to define the appropriate information and methods necessary for meeting the requirements of REACH. Pigments, surfactants, antioxidants, and complex chlorine substances are examples of classes of substances, which may require special considerations to take into account the testing requirements for complex substances. Recommendations for the assessment of natural complex substances like essential oils have been recently published (<http://echa.europa.eu/support/substance-identification/sector-specific-support-for-substance-identification/essential-oils>). Additional examples are presented in Section [R.7.13.1](#) and [R.7.13.2](#) for metal and inorganic substances and petroleum products, respectively.

#### R.7.13.1 Metals and Inorganics

Metals and inorganic metal compounds have properties which require specific considerations when assessing their hazards and risks. These considerations may include:

- 1 • The occurrence of metals as natural elements in food, drinking water and all  
2 environmental compartments
- 3 • The essentiality of some of the metals for humans and organisms living in the  
4 environment and their general relationship with the natural background
- 5 • The speciation of metals influencing bioavailability and for some even the  
6 hazard profile
- 7 • The short and long term bioavailability of metals and differing degrees of  
8 availability to humans and other organisms in the environment

9 The classical (eco-)toxicity tests do not necessarily consider the above properties and  
10 the results obtained may, therefore, be difficult to interpret. Taking specific  
11 considerations into account when testing metals and inorganic metal compounds could  
12 often prevent these. Extensive experience on hazard and risk assessment of metals was  
13 gathered under the Existing Substances Regulation programme and the technical and  
14 scientific knowledge with regard to metals has advanced significantly. These have been  
15 described in detail by Van Gheluwe *et al.* (2006) for the environment and Battersby *et*  
16 *al.* (2006) for human health. Specific guidance on testing and data interpretation for the  
17 hazard and risk assessment of metals and inorganic metal compounds is given in the  
18 chapters related to the individual endpoints.

### 19 **R.7.13.2 Petroleum Substances**

20 Petroleum substances belong to the group of UVCB substances: complex mixtures of  
21 hydrocarbons, often of variable composition, due to their derivation from natural crude  
22 oils and the refining processes used in their production. Many petroleum substances are  
23 produced in very high tonnages to a range of technical specifications, with the precise  
24 chemical composition of particular substances, rarely if ever fully characterised. Since  
25 complex petroleum substances are typically separated on the basis of distillation, the  
26 technical specifications usually include a boiling range. These ranges correlate with  
27 carbon number ranges, while the nature of the original crude oil and subsequent refinery  
28 processing influence the types and amount of hydrocarbon structures present. The CAS  
29 definitions established for the various petroleum substance streams generally reflect  
30 this, including details of final refinery process; boiling range; carbon number range and  
31 predominant hydrocarbon types present.

32 For most petroleum substances, the complexity of the chemical composition is such that  
33 it is beyond the capability of routine analytical methodology to obtain complete  
34 characterisation. Typical substances may consist of predominantly mixtures of straight  
35 and branched chain alkanes, single and multiple naphthenic ring structures (often with  
36 alkyl side chains), single and multiple aromatic ring structures (often with alkyl side  
37 chains). As the molecular weights of the constituent hydrocarbons increase, the number  
38 and complexity of possible structures (isomeric forms) increases exponentially.

39 Similar to the petroleum substances are the hydrocarbon solvents; they also consist of  
40 variable, complex mixtures of hydrocarbons and are described by EINECS numbers that  
41 are also used for petroleum refinery streams. Hydrocarbon solvents usually differ from  
42 petroleum refinery streams in the following ways:

- 43 • they are more highly refined;

- 1           • they cover a narrower range of carbon number;
- 2           • they contain virtually no substances of concern (e.g. benzene)
- 3           • they contain virtually no olefins.

4 Although compositionally somewhat better defined than the corresponding petroleum  
5 streams, hydrocarbon solvents require special consideration of the testing strategies  
6 similar to that of the petroleum substances.

7 Toxicity is defined via a concentration response and is dependant on the bioavailability of  
8 the individual constituents in a UVCB test substance. This may make interpretation for  
9 some substances very difficult. For example the physical form may prevent the  
10 dissolution of the individual constituents of such a substance to any significant extent  
11 where the whole substance is applied directly to the test medium. The consequence of  
12 this would be that toxicity may not be seen in such a test system. This would thus not  
13 allow for the toxicity assessment of these constituents to be addressed, were they to be  
14 released into the environment independent of the original matrix.

15 Testing strategies for environmental effects of petroleum substances necessarily reflect  
16 the complexity of their composition. Reflecting the properties of the constituent  
17 hydrocarbons, petroleum substances are typically hydrophobic and exhibit low solubility  
18 in water. However, reflecting the range of structures, constituent hydrocarbons will  
19 exhibit a wide range of water solubility. When adding incremental amounts of a complex  
20 petroleum substance to water, a point will be reached where the solubility limit of the  
21 least soluble component is exceeded and the remaining components will partition  
22 between the water and the undissolved hydrocarbon phases. Consequently, the  
23 composition of the total dissolved hydrocarbons will be different from the composition of  
24 the parent substance. This water solubility behaviour impacts on both the conduct and  
25 interpretation of aquatic toxicity tests for these complex substances, whilst the complex  
26 composition and generally low water solubility impacts on the choice and conduct of  
27 biodegradation studies.

28 For petroleum derived UVCBs, the lethal loading test procedure, also known as the WAF  
29 procedure provides the technical basis for assessing the short term aquatic toxicity of  
30 complex petroleum substances (Girling *et al.*, 1992). Test results are expressed as a  
31 lethal or effective loading that causes a given adverse effect after a specified exposure  
32 period. The principal advantage of this test procedure is that the observed aquatic  
33 toxicity reflects the multi-component dissolution behaviour of the constituent  
34 hydrocarbons comprising the petroleum substance at a given substance to water  
35 loading. In the case of petroleum substances, expressing aquatic toxicity in terms of  
36 lethal loading enables complex substances comprised primarily of constituents that are  
37 not toxic to aquatic organisms at their water solubility limits to be distinguished from  
38 petroleum substances that contain more soluble hydrocarbons and which may elicit  
39 aquatic toxicity. As a consequence, this test procedure provides a consistent basis for  
40 assessing the relative toxicity of poorly water soluble, complex substances and has been  
41 adopted for use in environmental hazard classification (UNECE, 2003). Complex  
42 substances that exhibit no observed chronic toxicity at a substance loading of 1 mg/l  
43 indicate that the respective constituents do not pose long term hazards to the aquatic  
44 environment and, accordingly, do not require hazard classification (CONCAWE, 2001;  
45 UNECE 2003).

1 There are two possible approaches for generating new information or interpreting  
2 existing information, bearing in mind the limitations on interpretation of the results  
3 mentioned above:

4 • First for petroleum substances, a model, PETROTOX, has been developed  
5 (Redman *et al.*, 2006), based on previous work assuming a non-polar narcosis  
6 mode of action (McGrath *et al.*, 2004; 2005). This model, which was  
7 developed to predict the ecotoxicity of petroleum substances and hydrocarbon  
8 blocks, could be used to address individual structures where no experimental  
9 data is available.

10 • The WAF loading concept may be used for environmental hazard classifica tion  
11 (GHS 2005), but should not be used for PBT assessment.

12 The complex composition and generally low water solubility also impacts the choice and  
13 conduct of biodegradation studies.

14 A further complication impacting both the choice of test method and interpretation of  
15 results is the volatility of constituent hydrocarbons, which shows a wide variation across  
16 the range of carbon numbers and hydrocarbon structures present in petroleum  
17 substances. It has been the practise to assess the inherent hazards of petroleum  
18 substances by conducting testing in closed systems (going to great lengths to ensure  
19 that volatile losses are minimised), even though under almost all circumstances of  
20 release into the environment, there would be extensive volatilisation of many of the  
21 constituent hydrocarbons.

22 Health effects testing strategies for petroleum substances also reflect the complexity of  
23 their composition and their physico-chemical properties. Key factors impacting both the  
24 choice of test method and interpretation of results are:

25 • the vapour pressure of constituent hydrocarbons, which show a wide variation  
26 across the range of carbon numbers and hydrocarbon structures present in  
27 petroleum substances. This will influence the physical nature of the material  
28 to which exposure occurs

29 • the lipid solubility of constituent hydrocarbons, which show a wide variation  
30 across the range of carbon numbers and hydrocarbon structures present in  
31 petroleum substances. This will influence the potential for uptake into body  
32 tissues

33 • the viscosity of the complex petroleum substance which can significantly  
34 impact on potential for dermal absorption

35 • the presence of small amounts of individual *hazardous* constituents in  
36 complex petroleum substances eg Poly Aromatic Hydrocarbons (PAH's), which  
37 may or may not be relevant to the toxicity of the complex petroleum  
38 substance

39 • the presence of other constituents in the complex mixture which may modify  
40 (inhibit or potentiate) the toxicity of hazardous constituents.

41 Toxicological evaluation of complex petroleum substances has normally been based on  
42 results of testing of the complete mixture, using OECD Guideline methods. Using this

1 approach it has been possible to take account of the complex interactions that occur  
2 between individual constituents of the mixture and the various physico-chemical  
3 properties that influence potential for exposure and uptake. In some cases however it  
4 has been necessary to adopt modified or non-standard test methods to provide a more  
5 reliable indication of the toxicity of certain petroleum fractions. The use of non-standard  
6 methods to evaluate the health and environmental effects of petroleum substances is  
7 described in more detail in the endpoint specific chapters.

**Appendix to Section R.7.13**

Appendix R.7.13-1 Technical Guidance for Environmental Risk Assessment of  
Petroleum Substances

## 1 **Appendix R.7.13-1 Technical Guidance for Environmental Risk** 2 **Assessment of Petroleum Substances**

### 4 **1.0 Introduction**

5 Petroleum substances typically consist of an unknown complex and variable composition  
6 of individual hydrocarbons. CAS numbers used to identify petroleum substances are  
7 based on various considerations including hydrocarbon type, carbon number, distillation  
8 range and the type and severity of processing used in substance manufacture.

9 To characterize hazards, CONCAWE (the oil companies' European organisation for  
10 environment, health and safety in refining and distribution) has grouped CAS numbers of  
11 petroleum substances derived from petroleum refining into generic categories of major  
12 marketed products (Boogard et. al, 2005). Further processing of these refinery streams  
13 can be performed to produce more refined hydrocarbon-based solvents. These products  
14 have also been further grouped to provide a consistent rationale for environmental  
15 hazard classification purposes (Hydrocarbon Solvents Producers Association, 2002).

16 Petroleum substances typically contain hydrocarbons that exhibit large differences in  
17 physio-chemical and fate properties. These properties alter the emissions and  
18 environmental distribution of the constituent hydrocarbons, and consequently it is not  
19 possible to define a unique predicted exposure concentration (PEC) for a petroleum  
20 substance. It is not, therefore, possible to directly apply current risk assessment  
21 guidance developed for individual substances to complex petroleum substances. To  
22 provide a sound technical basis to assess environmental exposure and risks of petroleum  
23 substances, CONCAWE devised the hydrocarbon block method (HBM) in which  
24 constituent hydrocarbons with similar properties are treated as pseudo-components or  
25 "blocks" for which PECs and predicted no effects concentrations (PNECs) can be  
26 determined (CONCAWE, 1996). Risks are then assessed by summing the PEC/PNEC  
27 ratios of the constituent blocks. While this conceptual approach has been adopted by  
28 the EU as regulatory guidance (EC, 2003) experience in applying this method was  
29 limited. Recent studies demonstrate the utility of the HBM to gasoline (MacLoed *et al.*,  
30 2004; McGrath *et al.*, 2004; Foster *et al.*, 2005) and further work has been on-going to  
31 support the practical implementation of the HBM methodology to higher boiling  
32 petroleum substances. The following section provides a concise overview of the key  
33 steps which comprise the HBM and it's application to the risk assessment of petroleum  
34 substances.

35

### 36 **2.0 Outline of Method**

37 Risk assessment of petroleum substances using the HBM involves an eight step process:

#### 38 2.1. Analyze petroleum substance composition & variability

39 The initial step involves analytical characterization of representative samples with  
40 different CAS numbers included in the petroleum substance category (e.g. kerosines, gas  
41 oils, heavy fuel oils, etc.). Analytical approaches used for this purpose are generally

1 based on chromatographic methodology and have been described previously (Comber *et al.*, 2006, Eadsforth *et al.*, 2006).

3 Options for analysis of petroleum substances that have been used include:

4 a. Full characterisation using GC can be performed on some simpler substances,  
5 e.g. gasoline. However, full characterization of higher boiling point streams is  
6 not feasible due to the increased complexity of the substances and rapidly  
7 increasing number of hydrocarbon components present in such substances.

8 b. "Modified" Total Petroleum Hydrocarbon (TPH) in which the aromatic and  
9 aliphatic fractions of the sample are first separated via a HPLC column. The  
10 hydrocarbon distribution in both fractions is then quantified as a function of  
11 equivalent carbon number using flame ionization detection. The equivalent  
12 carbon number (EC#) is defined by the elution time of the corresponding n-  
13 alkane standards. This approach has been adopted in risk-based assessment  
14 of petroleum contaminated sites (McMillen *et al.*, 2001). This method can be  
15 used to quantify hydrocarbons up to an EC# of ca. 120.

16 c. Two dimensional chromatography (2d-GC) uses the same initial fractionation  
17 step used in the above TPH method. Further resolution of the various aromatic  
18 (e.g. mono, di, tri, poly aromatic and partially hydrogenated aromatic ring  
19 classes) and aliphatic (e.g. n-paraffins, i-paraffins, monocyclics, dicyclics and  
20 polycyclic saturated ring structures) classes is achieved by the coupling of two  
21 columns, respectively based on volatility and polarity, in series. This high  
22 resolution method can be used to quantify hydrocarbons up to an EC# of ca.  
23 35. However, this method is limited to petroleum substances that contain a  
24 significant fraction of hydrocarbons below EC# 35 (Eadsforth *et al.*, 2006).

## 25 2.2 Select hydrocarbon blocks (HBs) to describe product composition

26 Given the type of compositional data obtained using the methods above, HBs can be  
27 selected on the basis of EC# (i.e. boiling point range) and low (aromatic vs. aliphatic  
28 classes) or high (up to 16 hydrocarbon classes) resolution blocking schemes. Within  
29 aromatic and aliphatic classes or sub-classes, variation in physico-chemical properties  
30 depends on the range of EC# used to define the block. Analyses from multiple samples  
31 should be used to determine the mean and variance of HB mass fractions that are  
32 representative for the petroleum substance category under investigation.

## 33 2.3. Define relevant physico-chemical and fate property data for HBs

34 In order to perform environmental fate and effects modeling, physico-chemical and fate  
35 properties must be assigned to HBs. To estimate HB properties, CONCAWE has  
36 developed a library of ca. 1500 individual hydrocarbon structures that attempts to  
37 represent the structural diversity of the hydrocarbons present in petroleum substances.  
38 For each structure, publicly available quantitative structure property relationships  
39 (QSPR) have been used predict key properties (e.g. octanol-water partition coefficient,  
40 vapour pressure, atmospheric oxidation half-life, fish bioconcentration factor), (Howard  
41 *et al.*, 2006). To estimate primary biodegradation half-lives for various compartments,  
42 literature data on hydrocarbons tested in unacclimated conditions involving mixed  
43 cultures under environmentally realistic conditions have been used to develop a  
44 hydrocarbon-specific QSPR (Howard *et al.*, 2005). This new QSPR has been applied to

1 estimate the half-life of representative library structures. Property data for individual  
2 library structures are then "mapped" to the corresponding HBs to assign HB property  
3 estimates. Due to the very low solubility of hydrocarbons with EC# > 35 in  
4 environmental media, these components are treated as inert constituents that are not  
5 considered further in exposure or effect assessment.

#### 6 2.4. Estimate environmental emissions of HBs throughout product lifecycle stages

7 Once HBs have been selected and properties defined, an emission characterization  
8 covering production, formulation, distribution, professional and personal use and waste  
9 life stages must be performed for the petroleum substance category. In addition to  
10 assessing the total magnitude of emissions into each environmental compartment (air,  
11 water and soil), it is also necessary to speciate these emissions in terms of the HB blocks  
12 selected that describe the petroleum product. As in the case of single substance risk  
13 assessments, emissions characterization must be considered at different scales (local,  
14 regional and continental) and determined using either measured, modeled or, in the  
15 absence of other information, conservative default emission factors that are derived  
16 given HB properties and product use categories.

#### 17 2.5. Characterize fate factors and intake fractions of HBs

18 To assess the environmental fate behavior of HBs, EUSES modeling has been performed  
19 for each library structure for different unit-emission scenarios (i.e. 100 kg/yr, 10 kg/yr  
20 or 1 kg/yr emission into air or water or soil at continental, regional and local scales,  
21 respectively). From these EUSES model runs, fate factors (fFs) and human intake  
22 fractions (iFs) for each emission scenario have been calculated. Fate factors for each  
23 compartment are defined as the calculated PEC in the compartment divided by the  
24 assumed emission for a given scenario. Intake fractions are defined as the predicted  
25 human exposure divided by the emission for a given scenario. This modeling exercise  
26 has provided a library of fFs and iFs for all representative hydrocarbon structures (van  
27 de Meent, 2007). This approach has the advantage that EUSES fate modeling only  
28 needs to be performed once so that results can then be consistently applied across  
29 different petroleum substance groups.

#### 30 2.6. Determine environmental & human exposure to HBs

31 To calculate compartmental PECs and human exposures for different spatial scenarios,  
32 block emissions for the scenario are first equally divided among representative  
33 structures that "map" to that block. Emissions are then simply multiplied by the  
34 corresponding fFs or iFs that correspond to that structure to scale the model predicted  
35 exposure or human intake to the actual emission. PECs or human exposures for the  
36 block are then calculated by summing results for all of the representative structures that  
37 comprise the block.

38 For petroleum substances use of environmental monitoring data needs specific  
39 consideration. While data may be available for "total" hydrocarbons or specific  
40 hydrocarbon structures (e.g. naphthalene, chrysene), the source of these constituents  
41 may be multiple anthropogenic and natural sources. Therefore, such release or  
42 monitoring data may be only used to provide a worst-case, upper bound estimate of the  
43 concentration of a "block" for screening purposes. In contrast, model derived PECs are  
44 intended to provide a more realistic estimate for substance risk assessment since these

1 values represent only the fraction of the observed total concentration of the "block" in  
2 the environment that is attributable to the specific petroleum substance under study.

### 3 2.7. Assess environmental effects of HBs

4 Since petroleum substances are comprised principally of only carbon and hydrogen,  
5 these substances will exert ecotoxicity via a narcotic mode of action (Verhaar *et al.*,  
6 2000). Moreover, ecotoxicity endpoints for narcotic mixtures are generally observed and  
7 quantitatively modeled as simply additive (de Wolf *et al.*, 1988; McGrath *et al.*, 2005;  
8 DiToro *et al.*, 2007). To assess the environmental effects of HBs comprising petroleum  
9 substances on aquatic and wastewater organisms, a modification of the target lipid  
10 model (McGrath *et al.*, 2004; Redman *et al.*, 2007) has been developed that builds on  
11 the work by Verbruggen (2003) in which toxicity relationships are related to membrane-  
12 water rather than octanol-water partition coefficients (Redman, 2007). This revision is  
13 needed to allow extension of the target lipid model to more hydrophobic constituents,  
14 beyond gasoline range hydrocarbons, that are present in many petroleum substances.  
15 The revised target lipid model has been used to derive PNECs for all CONCAWE library  
16 structures. If coupled with equilibrium partitioning theory, this model framework can  
17 also be used to support effects assessment in the soil/sediment compartment (Redman  
18 *et al.*, 2007b).

### 19 2.8. Evaluate individual and aggregate risk of HBs

20 To assess environmental risks, the PEC/PNEC ratio for each library structure within a  
21 block is calculated and then the ratios for different structures summed within each block.  
22 The additive risk contributed by all the blocks is then determined to estimate the risk of  
23 the petroleum substance group. This calculation is performed for each spatial scale.

24 Efforts are currently underway to automate the HBM method into a simple spreadsheet-  
25 based computational tool. This tool is intended to provide a generic methodology to  
26 support petroleum substance risk assessment that: (1) links analytical characterization  
27 of petroleum substances to HB definition; (2) provides a consistent technical framework  
28 across different petroleum groups; (3) reflects the current state of science; and (4) is  
29 transparent and practical in scope. Availability of this tool will also allow the sensitivity  
30 of risk characterisation to be assessed in response to changes in compositional  
31 assumptions or alternative "blocking" schemes. Moreover, this tool will enable  
32 identification of HBs which are principal contributors to the PEC/PNEC ratio and where  
33 refinement in further data collection can be logically focused if the estimated PEC/PNEC  
34 > 1.

35

## 36 **3.0 Limitations**

37 At present the current HBM methodology does not quantitatively address effects on the  
38 air compartment due to lack of standardised laboratory hazard data. In addition, the  
39 method does not address heterocyclic compounds (e.g. carbazoles in cracked fuels) or  
40 metals (e.g. vanadium and nickel in fuel oils and asphalt) which may be present at low  
41 levels in certain petroleum substances. The potential for reduced exposure of certain  
42 polyaromatic hydrocarbons as a result of photodegradation or enhanced toxicity due to  
43 photoactivation is also not addressed due to the complexity and site-specific nature of

1 these processes. Nevertheless, these issues may be considered on a case-by-case basis,  
2 at least in a qualitative manner.

3 The scope of the generic methodology is intended to address the risks posed by  
4 hydrocarbon components in petroleum substances. Therefore, additives that are  
5 intentionally introduced to modify the technical properties or performance of petroleum  
6 substances are outside the scope of this methodology, but in any event, these  
7 substances will be subject to independent risk assessments. Likewise, secondary  
8 constituents that are generated from reactions resulting from petroleum substance use  
9 (e.g. combustion by-products other than hydrocarbons components in the substance)  
10 are excluded and addressed by other EU and country-specific regulations.

**Appendix to Chapter R.7**

## Appendix R.7—1 Threshold of Toxicological Concern (TTC) – a concept in toxicological and environmental risk assessment

### Human Health Aspects

Risk assessment for human health effects is based on the threshold of a critical toxicological effect of a chemical, usually derived from animal experiments. Alternatively, a toxicological threshold may also be based on the statistical analysis of the toxicological data of a broad range of structurally-related or even structurally-different chemicals and extrapolation of the no effect doses obtained from the underlying animal experiments for these chemicals to levels considered to be of negligible risk to human health. This latter approach refers to the principle called Threshold of Toxicological Concern (TTC). Regarded in this way the TTC concept could be seen as an extension of such approaches read-across and chemical category. As such, the TTC concept has been incorporated in the risk assessment processes by some regulatory bodies, such as the U.S Food and Drug Administration (FDA) and the UN JMPR and EU EFSA in the assessment of flavourings and food contacts articles (SCF, 2001), as an approach to identify exposure levels of low regulatory concern, and as a tool to justify waiving of generation of animal data.

This section will briefly discuss different TTC approaches, their limitations, criteria for use, and finally their potential use under REACH.

#### TTC approaches

The TTC was implemented by the FDA as the *Threshold of Regulation* from food contact materials since 1995; a TTC value of 1.5 µg per person per day was derived for a chemical database that covered carcinogenicity (i.e. their calculated one per million risk levels; Gold *et al.*, 1995). This value is considered to be applicable for all endpoints except genotoxic carcinogens.

Munro *et al.* (1996) subsequently developed a structure-based TTC approach on principals originally established by Cramer *et al.* (1978). The structural classes of organic chemicals analysed showed significantly different distributions of NOEL's for subchronic, chronic and reproductive effects. Carcinogenic or mutagenic endpoints were not considered. Based on the chemical structure in combination with information on toxicity three different levels (90, 540 and 1800 µg per person per day, respectively) were derived. UN-JMPR and EU EFSA have implemented these values in the regulations for indirect food additives.

Another structure-based, tiered TTC concept developed by Cheeseman *et al.* (1999), extended the Munro *et al.* (1996) 3 classes approach by incorporated acute and short-term toxicity, mutagenic and carcinogenic potency (but exempting those of high potency).

More recently, Kroes *et al.* (2004) evaluated the applicability for different toxicological endpoints, including neurotoxicity and immunotoxicity, and proposed a decision tree with 6 classes of organic chemicals. Allergens or substances causing hypersensitivity could

1 not be accommodated due to the lack of an appropriate database (enabling statistical  
2 analysis for this category of substances).

3 Apart from the two indicated cases, the other approaches have not been adopted by any  
4 regulatory body.

5 Recently, ECETOC has proposed a Targeted Risk Assessment approach for REACH  
6 including a series of threshold values for a wide variety of organic and non-organic  
7 substances (both volatile and non-volatile), i.e. so-called Generic Exposure Value (GEV),  
8 and Generic Lowest Exposure Value (GLEV) for acute and repeated dose toxicity  
9 (ECETOC, 2004). Category 1 and 1B carcinogens, mutagens and reprotoxins were  
10 excluded. The GEV is a generic threshold values for occupational exposure (and derived  
11 dermal values), derived from some most stringent Occupational Exposure Limits (OEL).  
12 The GLEV is based on classification criteria for repeated dose toxicity and extrapolation  
13 factors. It is noted that the derivation of GEV values was based upon an analysis of  
14 current published occupational exposure levels, and therefore also incorporated socio-  
15 economic and technical arguments in addition to the assessment factors applied to  
16 toxicological endpoints and other data on which the OELs were based. This approach has  
17 not been peer reviewed nor accepted by regulatory bodies.

#### 18 Basic requirements

19 The TTC concept discussed above require a minimum set of information in order to be  
20 applied successfully. However it should be noted that the application of TTC excludes  
21 substances with certain structural elements and properties including:

- 22 • Non-essential, heavy metals and polyhalogenated dibenzodioxins, -  
23 dibenzofurans, or-biphenyls and similar substances:  
24 This class of substances cannot be addressed by the TTC concepts due to the  
25 bio-accumulating properties. Although the TTC approach is able to  
26 accommodate other categories of substances with bio-accumulating potential,  
27 within the regulatory context, substances with potential for bioaccumulation  
28 are 'of concern' and need to be assessed on a case-by-case basis. Potentially  
29 bioaccumulating or persistent substances are also excluded from default  
30 environmental risk assessments.
- 31 • Genotoxic carcinogens:  
32 A case-by-case risk assessment is required for genotoxic carcinogens, even  
33 though some carcinogens can be accommodated within the TTC concept if the  
34 estimated intake is sufficiently low (<0.15 µg/day).
- 35 • Organophosphates:  
36 This class of high potency neurotoxicants are excluded.
- 37 • Proteins:  
38 This class of substances is a surrogate to address specifically potential (oral)  
39 sensitisation, hypersensitivity and intolerances. There are no appropriate  
40 databases available which allow the derivation of a generic threshold for this  
41 type of endpoint.

42 Additionally, another very critical criterion concerns the knowledge on the handling and  
43 use of the substance. TTC is only applicable in case there is detailed information

1 available on all anticipated uses and use scenarios for which the risk assessment is  
2 provided.

### 3 Limitations

4 The TTC has several limitations. First of all, they are derived on data bases covering  
5 primarily systemic effects from oral exposure. This is especially important concerning  
6 occupational situations where inhalation or dermal exposure is the main route of contact.  
7 Only some cover mutagenic, carcinogenic and acute effects, and in fact none (except for  
8 the proposed ECETOC approach) addresses local effects such as irritation and  
9 sensitisation.

10 As all TTC approaches (except for the proposed ECETOC approach) have oral exposure  
11 as the principle route, further substantial efforts are needed to explore its potential use  
12 for the exposures routes inhalation and skin contact, before any application may become  
13 realistic.

14 Several of the structurally-based approaches to TTC have limitations in applicability  
15 domain and cannot accommodate every chemical class. For instance, proteins, heavy  
16 metals, polyhalogenated-dibenzodioxins, aflatoxin-like substances, N-nitroso-  
17 compounds, alpha-nitro furyl compounds and hydrazins-, triazenes-, azides-, and azoxy-  
18 compounds have been excluded by the approach of Kroes *et al.* (2004). Also excluded  
19 are highly potent neurotoxicants, organophosphates and genotoxic carcinogens.

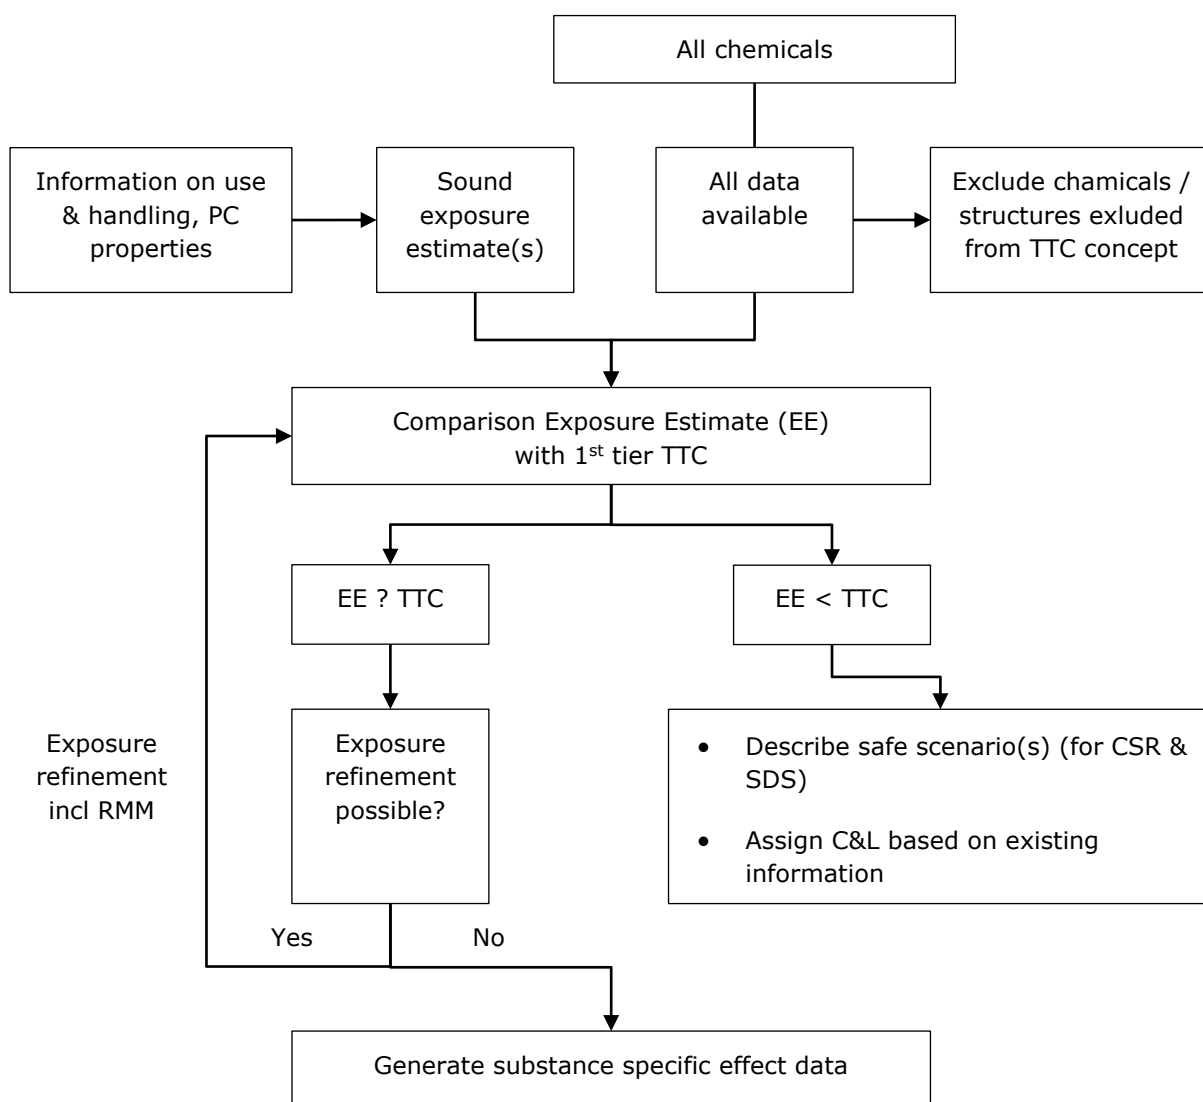

20 As indicated, the TTC approach is only applicable in case there is detailed information  
21 available on all anticipated uses and use scenarios for which the risk assessment is  
22 provided. Based on the experience of the EU Risk Assessment Programme for Existing  
23 Substances, robust exposure estimates will require a significant effort, even in cases  
24 where the uses were well characterised. In case of a multitude of (dispersive) uses and  
25 applications, it may not be feasible to generate overall exposure estimate with detail and  
26 precision necessary for use in a risk assessment relying on the thresholds based on the  
27 TTC concept. Therefore, a TTC will in practice only be applicable in those cases where  
28 there are only a few number of exposure scenario's that allow well characterisation.

29 Furthermore, the use of the TTC approach does not provide information on classification  
30 and labelling of a chemical, or on its potency for a specific effect.

### 31 Use of the TTC concept

32 The TTC concept has been developed primarily for use within a risk assessment  
33 framework. As already indicated, the TTC concept is applied for regulatory purposes by  
34 the U.S FDA and the EU EFSA and UN JMPR in the assessment of food contact articles  
35 and flavourings, respectively. These specific TTC approaches underwent a critical review  
36 before being accepted on this regulatory platform. Clearly, in the same way, any other  
37 TTC approach should be agreed upon by the relevant regulatory body before use, and it  
38 should be clearly indicated for which endpoints, routes and population they apply.

1 **Figure R.7.13–1 Generic TTC scheme/concept under REACH.**

The figure illustrates the way a TTC can be used: it precedes any chemical-specific testing. One tier is shown, but one could apply additional tiering rounds (as clearly illustrated by the approach presented by Kroes *et al.*, 2004) dependent upon the chemical of interest.

2

3 Potential use within REACH

4 It is feasible that within REACH the TTC concept may be of use for the chemical safety  
5 assessment at tonnage levels triggering limited information on repeated dose toxicity  
6 and/or reproduction: REACH clearly indicates the need for non-testing methods and  
7 provides the opportunity of waiving testing based on exposure considerations. When  
8 clearly documented and justified the following options could apply.

9

### 1 REACH Annex VII

2 The testing requirements specified in Annex VII would normally not trigger toxicity  
3 testing involving repeated exposures and the information at this tonnage level do  
4 provide insufficient information to determine a dose descriptor or any other starting  
5 point for the derivation of a DNEL for use in an assessment of the human health risks  
6 associated with repeated exposures. Although non-testing or *in vitro* methodologies may  
7 give insight in the toxicological properties of a substance, generally such methods are  
8 insufficiently specific to provide quantitative information on the potency and/or threshold  
9 of an adverse effect. In such a case the threshold derived from the TTC methodology  
10 might provide a reference value to assess the significance of the human exposure.

### 11 REACH Annex VIII-X

12 At these tonnage levels there may be circumstances triggering an adaptation of the  
13 REACH requirements that may lead to waiving of the repeated dose toxicity study and,  
14 consequently, the generation of a substance-specific dose descriptor or another starting  
15 point for the derivation of a DNEL:

- 16 • in Annex VIII, repeated dose toxicity (28 d test, 8.6) and reproductive toxicity  
17 testing (8.7) may be waived if relevant human exposure can be excluded in  
18 accordance with Annex XI section 3.
- 19 • in Annex IX and X testing could be waived in case there is no significant  
20 exposure, and there is low toxicity, and no systemic exposure.

21 In a case-by-case consideration, the appropriate threshold derived from the TTC  
22 methodologies agreed upon by the relevant regulatory body might be considered as a  
23 starting point to assess the significance of the human exposure. The level chosen will be  
24 critical to ensure a level of sufficient protection.

### 25 Final remark

26 Independent of the approach used in risk assessment of industrial chemicals it is  
27 important to maintain a sufficient level of protection. In the striving for alternatives to  
28 animal testing one suggested approach is the use of generic threshold values. However,  
29 application of TTC would imply that limited data may be generated and thus, that the  
30 level of protection might be influenced. From information on flavouring substances in the  
31 diet the TTC concept seems to be reasonable well based with respect to general toxicity  
32 and the particular endpoints examined. However, the possible application of TTC on  
33 industrial chemicals needs to be carefully considered. There may be some important  
34 differences between industrial chemicals and substances used for food contact articles or  
35 flavourings, such as differences in use pattern and composition (for a further discussion  
36 see Tema Nord, 2005; COC, 2004).

37

38

## 1 **TTC concept for the environment\***

### 2 Two approaches

3 Two different approaches have been used when deriving a TTC for the environment, i.e.  
4 the *action-limit* proposed by EMEA/CPMP (2001) and the environmental Exposure  
5 Threshold of No Concern (ETNC) proposed by ECETOC (2004) and de Wolf *et al.* (2005).  
6 Both these approaches are restricted to the pelagic freshwater compartment.

7 1. The first of these TTC-approaches, i.e. the *action-limit*, originates from a draft  
8 on environmental risk assessment of human pharmaceuticals (EMEA/CPMP,  
9 2001), describing a tiered risk assessment process. The initial step is an  
10 environmental exposure assessment in which a coarsely predicted  
11 environmental freshwater concentration (PEC) for the pharmaceutical  
12 ingredient, or its major metabolites, is compared to an action limit (0.01  
13 µg/L). In case the PEC is smaller than the action-limit and no environmental  
14 concerns are apparent, no further action is considered needed. On the other  
15 hand, when the PEC is larger than the action-limit, the assessment continues  
16 to a second phase, which involves an environmental fate and effect analysis.  
17 The action limit is based on an aquatic concentration below which it was  
18 concluded that no ecotoxicity data on drugs for relevant standard test  
19 organisms were reported (U.S. FDA, 1996). This concentration was further  
20 divided by an assessment factor of 100 to obtain the action limit. The action-  
21 limit has been questioned by the CSTEE since drugs with lower effect  
22 concentrations were found. In addition, the focus on acute toxicity in the draft  
23 was questioned, as chronic toxicity was considered more relevant for this kind  
24 of substances, i.e. pharmaceuticals.

25 2. A different TTC-approach was applied deriving an ETNC for the pelagic  
26 freshwater compartment, i.e. ETNC<sub>aquatic</sub> (ECETOC, 2004; de Wolf *et al.*,  
27 2005). This approach was based on existing toxicological databases and  
28 substance hazard assessments for organisms in the freshwater environment,  
29 and a categorisation of chemicals into four different modes of action (MOA)  
30 according to the system by Verhaar *et al.* (1992). The stratified data was  
31 fitted to a lognormal distribution from which a fifth percentile, with a 50%  
32 confidence interval, was determined. This value was then divided by an  
33 assessment factor, ranging from 1 to 1000 depending on the data to obtain  
34 the ETNC<sub>aquatic</sub>. Metals, inorganics, and ionisable organic chemicals are not  
35 covered by this system, and thus not included when deriving the ETNC<sub>aquatic</sub>.

36  
37 The authors proposed an overall value of 0.1µg/L for MOA1-3. The authors  
38 considered that a broad application of the ETNC<sub>aquatic</sub> concept also needed to  
39 cover MOA4, and that the resulting ETNC<sub>aquatic</sub> likely would have to be much  
40 lower. This idea is substantiated by the fact that a substantially lower  
41 ETNC<sub>aquatic</sub> was observed when analysing the chemicals assigned a MOA4,

---

\* Based on TemaNord 2005: 559.

1 as the resulting ETNCAquatic, MOA4 was 0.0004 µg/l. The lowest individual  
2 NOEC value in that particular database was 0.0006 µg/l (Fenthion).

### 3 Regulatory use

4 There is presently no use of the TTC concept as regards environmental assessments.  
5 However, in a draft by EMEA/CPMP (2001, 2005) a stepwise, tiered procedure for the  
6 environmental risk assessment of pharmaceuticals (for human use) is proposed. This  
7 approach would involve a TTC approach as it includes an action limit of 0.01 µg/l in  
8 pelagic freshwater environment.

9 The ETNC may be considered a risk assessment tool, and data might still be needed for  
10 classification or PBT assessment. In general, acute toxicity data will be  
11 available/predictable, and the resulting PNEC will often be above the ETNC. If it is lower,  
12 then the substance should be considered in more depth.

### 13 Discussion

14 The TTC-concept represents a new approach as regards environmental risk assessments  
15 since it results in a general PNEC (a non-effect threshold value) that is intended to be  
16 applied on an entire group of substances, as compared to the standard substance  
17 specific PNEC.

18 The TTC approach is developed only for direct effects on the pelagic freshwater  
19 ecosystem and not effects due to bioaccumulation, or accumulation in other  
20 compartments. In addition, the concept does not cover metals, other inorganic  
21 compounds, or ionisable organic compounds. The use of the threshold of no toxicological  
22 concern, as compared to experimental data, implies a higher risk of not considering the  
23 toxicity of degradation product(s)/metabolite(s), which may be unfortunate if they are  
24 more toxic than the parent compound.

25 It has been proposed by de Wolf *et al.*, 2005 to use the TTC concept as a tool for  
26 screening in order to select/prioritise substances for testing/further risk assessment, e.g.  
27 it may help to inform downstream users about the relative risk associated with their  
28 specific uses. The approach could also be valuable in putting environmental monitoring  
29 data into a risk-assessment perspective. For these applications the concept may work if  
30 the TTC is satisfactory determined. However, because only toxicity is considered, P and  
31 B criteria should also be consulted. The main reason using the TTC approach would be  
32 the saving of aquatic freshwater test organisms, including vertebrate species (mainly  
33 fish).

34 The method of deriving a PNEC, using the NOEC for the most sensitive species and an  
35 assessment factor, is the standard approach in TGD to derive a threshold value, i.e.  
36 Predicted No Effect Concentration (PNEC), for a chemical. Instead of using NOECs for the  
37 most sensitive species, it has for some data rich substances (e.g. Zn in the Existing  
38 Substance Regulation) been accepted to instead use the 5th percentile and lognormal  
39 distribution, of all species from all phyla, to derive a NOEC. This since the traditional  
40 method of deriving PNEC, according to the TGD, for the data rich metals resulted in  
41 PNECs below background values. In these cases, ecotoxicity data for a number of  
42 species and phyla was used to derive a toxicity threshold (PNEC) for one substance. This  
43 differs from the ETNCAquatic (TTC)-approach, where instead an assessment factor is  
44 used on the fifth percentile of toxicity data for the many species for many chemicals

1 (belonging to a defined group). In the first case, the concept accepts that 5% of the  
2 species NOECs will fall below the threshold. In the second case, the concept accepts that  
3 5% of the chemical PNECs will fall below the threshold. Is the safety level for the  
4 environment similar in these two cases? The consequences should be further evaluated.

5 What is the added value of using a generic PNEC as compared to (Q)SAR estimates,  
6 when no substance specific experimental toxicity data is available? As regards what  
7 Verhaar *et al.* (1992) defined as mode of action 1-2, available QSAR models exist,  
8 which are based on more specific data, which should be more relevant than a generic  
9 TTC. However, it should be stressed that QSARs are usually used as indicators of an  
10 effect, and not for confirmation of lack of effects (which is the opposite of how the TTC is  
11 proposed to be used!).

12 If the TTC-concept is to be used, should one or several threshold values be used? Using  
13 more than one threshold value implies a higher risk of using the wrong (not safe)  
14 threshold. The use of several thresholds put higher demands on the categorisation  
15 system. Chemicals may be categorised according to different systems. Considering the  
16 fact that the knowledge in this field has continued to grow over the years, is the  
17 approach suggested thirteen years ago by Verhaar *et al.* (1992), as proposed by ECETOC  
18 (2004) and de Wolf *et al.* (2005), presently the most appropriate way of grouping  
19 chemicals in order to derive a TTC? This method uses four modes of toxic action to  
20 differentiate between chemicals. Even though rules exist as to categorise that a  
21 chemical exhibits one of the first of these three modes of action, it is however not  
22 possible, based on definite structural rules, to decide whether or not a substance exhibits  
23 the fourth of these modes. Inclusion in this fourth class must, and should, be based on  
24 specific knowledge on mode of toxic action of (groups of) chemicals. In addition, a  
25 substance may have more than one mode of action.

26 Hence, the use of only one threshold value appears to be the most transparent and  
27 conservative approach. As a consequence of the above, it seems reasonable to base this  
28 threshold value on chronic toxicity data for the most toxic chemicals, i.e. those  
29 categorised as having a specific mode of toxic action.

30 TTC can presently not be used as a stand-alone concept, but could perhaps in the future  
31 be included in a *Weight-of-Evidence* approach when deciding on potential derogations.
